

QUANTIFYING THE SOURCES OF FIRM HETEROGENEITY*

COLIN J. HOTTMAN
STEPHEN J. REDDING
DAVID E. WEINSTEIN

We develop and structurally estimate a model of heterogeneous multiproduct firms that can be used to decompose the firm-size distribution into the contributions of costs, “appeal” (quality or taste), markups, and product scope. Using Nielsen barcode data on prices and sales, we find that variation in firm appeal and product scope explains at least four fifths of the variation in firm sales. We show that the imperfect substitutability of products within firms, and the fact that larger firms supply more products than smaller firms, implies that standard productivity measures are highly dependent on implicit demand system assumptions and probably dramatically understate the relative productivity of the largest firms. Although most firms are well approximated by the monopolistic competition benchmark of constant markups, we find that the largest firms that account for most of aggregate sales depart substantially from this benchmark, and exhibit both variable markups and substantial cannibalization effects. *JEL* Codes: L11, L21, L25, L60.

I. INTRODUCTION

Why are some firms larger than others? Some companies, such as the Coca-Cola Company, generate billions of dollars of sales and dominate the markets in which they operate. Other companies account for only a small fraction of the sales of their larger competitors. What explains these vast differences in firm performance? Answering this question is important for quantifying equilibrium models of firm heterogeneity developed in the recent trade and macro literatures and for understanding the

relationship between microeconomic firm performance and macroeconomic outcomes.

Recent research on firm heterogeneity in trade and macroeconomics (e.g., [Melitz 2003](#); [Manova and Zhang 2012](#); [Feenstra 2014](#)) points to four components of firm heterogeneity: marginal cost, “appeal” (quality or taste), markups, and product scope (i.e., the number of products produced by firms).¹ We develop a structural model of heterogeneous multiproduct firms that can be used to decompose the firm-size distribution into the relative contributions of each component. We use this framework to structurally estimate elasticities of substitution across varieties between and within multiproduct firms. We implement our model-based decomposition for around 20,000 firms that supply goods with barcodes in the Nielsen HomeScan Database in a typical quarter. This decomposition uses the structure of the model to isolate different margins in the data without making assumptions about how those margins are related (as in the business cycle decomposition of [Chari, Kehoe, and McGratten 2007](#) in the macroeconomics literature). Our framework requires only price and expenditure data and hence is widely applicable. We separate out the contributions of cost and appeal using the exclusion restriction that cost only affects sales through price. In contrast, appeal affects sales conditional on price.

Our results point to demand differences (which could arise from quality or taste variation) as being the principal reason some firms are successful in the marketplace and others are not. Depending on the specification considered, we find that 50–70% of the variance in firm size can be attributed to differences in firm appeal, about 20–25% to differences in product scope, and less than 25% to cost. When we turn to examine time-series evidence, the results become even more stark. Virtually all firm growth can be attributed to firm appeal, with most of the remainder due to product scope. These results suggest that most of what

1. Much of the existing empirical literature refers to any shifter of demand conditional on price as “quality,” as in [Shaked and Sutton \(1983\)](#), [Berry \(1994\)](#), [Khandelwal \(2010\)](#), [Broda and Weinstein \(2010\)](#), [Hallak and Schott \(2011\)](#), and [Feenstra and Romalis \(2014\)](#). We use the term “appeal” to avoid taking a stand as to whether the shift in demand arises from vertical quality differentiation or subjective differences in consumer taste. Empirically, we find that higher appeal products are on average more costly to produce, which is consistent with a quality interpretation.

economists call differences in revenue productivity reflects differences in appeal (e.g., quality or taste) rather than cost.

Our framework uses a nested constant elasticity of substitution (CES) utility system that allows the elasticity of substitution between varieties within a firm to differ from the elasticity of substitution between varieties supplied by different firms. Our choice of this CES demand structure is guided by its prominence, tractability, and empirical feasibility. Across international trade, economic geography, and macroeconomics, there is little doubt that this framework is the preferred approach to modeling product variety. Since our approach nests the standard CES–monopolistic competition model as a special case, we can compare our results with those that would be obtained in a standard trade, macro, or economic geography model. However, we generalize this standard model to allow firms to supply multiple products (a pervasive feature of our data) and have market power (since the largest firms in our data are far from being measure zero).

Incorporating these features into our structural model yields a number of additional insights. Our model makes clear a conceptual problem in the estimation of firm productivity that is likely to bias existing estimates. Most productivity estimates rely on the concept of real output, which is calculated by dividing nominal output by a price index. However, the formula for any economically motivated price index, which is the same as a unit expenditure function, is dependent on implicit assumptions about how the output of firms enters utility. Thus, one cannot move from nominal output to real output without imposing assumptions about the structure of the demand system.² Our results show theoretically and empirically that the CES measure of a multi-product firm's price is highly sensitive to how differentiated its output is and how many products it supplies. The sensitivity of the CES price index to demand parameters, such as the elasticity of substitution and whether multiproduct firms exist, implies that estimates of real output are equally sensitive to these demand parameters. We show that if demand has a nested CES structure, conventional measures of real output will have a

2. This point was stressed by Aristotle in *Nicomachean Ethics* (Book V, Section 5): "Demand holds things together as a single unit. . . . In truth it is impossible that things differing so much should become commensurate, but with reference to demand they may become so" (see <http://classics.mit.edu/Aristotle/nicomachaen.5.v.html>).

downward bias that rises with firm size with an elasticity of around one third. In other words, real output variation is substantially greater than nominal output variation. This bias also implies that true productivity differences are much larger than conventionally measured ones.

The bias is driven by two features of reality that are typically ignored in most analyses. First, most analyses treat producers as single-product firms so they can avoid complications arising from the challenges of measuring the real output of multiproduct firms. However, our results indicate that multiproduct firms are the norm. For example, we show that 69% of firms supply more than one barcode and these firms account for more than 99% of output in their sectors.³ Therefore truly single-product firms account for a negligible share of sales in our data. Second, we show that if the output of multiproduct firms is differentiated, the common assumption that total firm output is simply the sum of the output of each good understates real output for multiproduct firms, and the degree of this downward bias rises in the number of products supplied.

Our framework also provides a new metric for quantifying the extent to which a firm's products are differentiated from those of its rivals. If a firm's products are perfectly substitutable with each other but not with those of other firms, then 100% of a new product's sales will come from the firm's existing sales, which implies a cannibalization rate of 1. However, if a firm's market share is negligible (as it is for most firms) and its products are as differentiated from each other as they are from products supplied by other firms, none of a new product's sales will come at the expense of the firm's other products, which implies a cannibalization rate of 0. We estimate that the cannibalization rate for the typical firm is about 50%, indicating that although products supplied by the same firm are more substitutable with each other than with those of other firms, it is not correct to think of them as perfect substitutes.

We find that the typical sector is characterized by a few large firms with substantial market shares and a competitive fringe of firms with trivial market shares. Firms from this competitive

3. By contrast, U.S. Census of Manufactures data indicate that producers of multiple five-digit SIC products account for 37% of firms and 87% of shipments (Bernard, Redding, and Schott 2010). The difference comes from defining single product firms as one-industry firms as opposed to one-barcode firms.

fringe choose prices close to the benchmark of monopolistic competition, because they have market shares too small to exploit their market power. However, the very largest firms that account for disproportionate shares of sales within product groups have substantially higher markups. This variation in markups is greater under quantity competition than under price competition. In most sectors, the largest firm has a market share above 20%, which enables it to charge a markup that is 24% higher than that of the median firm under price competition and double that of the median firm under quantity competition. We use the model to undertake counterfactuals, in which we show that these variable markups for the largest firms have quantitatively relevant effects on the firm-size distribution and aggregate consumer price indexes. Our counterfactual estimates indicate that the multiple varieties supplied by multiproduct firms reduce the consumer price index by around one third.

The remainder of the article is structured as follows. [Section II](#) reviews the related literature. [Section III](#) discusses the data. [Section IV](#) introduces the model. [Section V](#) uses the structure of the model to derive moment conditions to estimate elasticities of substitution and undertake our decomposition of firm sales. [Section VI](#) presents our estimation results. [Section VII](#) reports the results of a number of robustness tests. [Section VIII](#) undertakes counterfactuals. [Section IX](#) concludes.

II. RELATED LITERATURE

Over the past decade, the fields of international trade and macroeconomics have undergone a transformation as the dissemination of micro data sets and the development of new theories has led to a shift in attention toward firm heterogeneity. Existing research has suggested a number of candidate explanations for differences in firm performance, including differences in production efficiency ([Melitz 2003](#)), demand in the form of product quality ([Sutton 1991](#); [Schott 2004](#); [Khandelwal 2010](#); [Hallak and Schott 2011](#); [Johnson 2012](#); [Di Comite, Thisse, and Vandenbussche 2014](#); [Eslava, Fieler, and Xu 2014](#); [Feenstra and Romalis 2014](#)), markups ([De Loecker and Warzynski 2012](#); [De Loecker et al. 2016](#)), fixed costs ([Das, Roberts, and Tybout 2007](#)), and the ability to supply multiple products ([Arkolakis and Muendler 2010](#); [Bernard, Redding, and Schott 2010, 2011](#);

Eckel and Neary 2010; Mayer, Melitz, and Ottaviano 2014; Eckel et al. 2015). While existing research typically focuses on one or more of these candidate explanations, they are all likely to operate to some degree in the data. We develop a general theoretical model that incorporates each of these candidate explanations and estimate that model structurally using disaggregated data on prices and sales by firm and product. We use the estimated model to provide evidence on the quantitative importance of each source of firm heterogeneity and the ways they interact.

In much of the literature on firm heterogeneity following Melitz (2003), marginal cost and appeal (quality or taste) are isomorphic. Under the assumption of CES preferences and monopolistic competition, cost and appeal enter equilibrium firm revenue in the same way. However, these different sources of firm heterogeneity have different implications for firm revenue conditional on prices (Berry 1994; Khandelwal 2010). While marginal cost affects firm revenue through prices, appeal affects firm revenue conditional on prices. Thus, if two firms charge the same price, but one firm has a more appealing (e.g., higher quality) product than the other, that firm will generate more sales. An advantage of our approach is that we observe prices and sales in our data, and hence we are able to separate out cost and appeal as sources of dispersion in firm sales.⁴

Most of the existing research on firm heterogeneity in trade and macroeconomics has assumed that firms are measure zero and compete under conditions of monopolistic competition (Melitz 2003; Melitz and Ottaviano 2008). In contrast, a small number of papers have allowed firms to be large relative to the markets in which they operate (Atkeson and Burstein 2008; Amiti, Itskhoki, and Konings 2014; Edmond, Midrigan, and Xu 2015). When firms internalize the effects of their decisions on market aggregates, they behave systematically differently from measure zero firms. Even under CES demand, firms charge variable markups, because each firm internalizes the effects of its pricing decisions on market price indexes and these effects are greater for larger firms.⁵ Furthermore, since firms are of positive measure,

4. Our CES formulation of market demand can be derived from a discrete choice model of the demands of individual consumers, as shown in Anderson, de Palma, and Thisse (1992).

5. Our model generates variable markups without a “choke price” above which demand is zero. Therefore this model lies outside the classes considered by Arkolakis, Costinot, and Rodríguez-Clare (2012) and Arkolakis et al. (2015), in

idiosyncratic shocks to these “granular” firms can affect aggregate outcomes, as in [Gabaix \(2011\)](#) and [Di Giovanni and Levchenko \(2012\)](#). In contrast to these papers, we structurally estimate a model of heterogeneous firms and show how it can be used to recover the determinants of firm sales dispersion and undertake counterfactuals.

To the extent that such large firms supply multiple products, they take into account the effect of introducing new varieties on the sales of existing varieties. Most of the existing theoretical research on multiproduct firms in trade and macroeconomics has abstracted from these cannibalization effects by again assuming measure zero firms ([Allanson and Montagna 2005](#); [Agur 2010](#); [Arkolakis and Muendler 2010](#); [Bernard, Redding, and Schott 2010, 2011](#); [Mayer, Melitz, and Ottaviano 2014](#); [Nocke and Yeaple 2014](#)). Important exceptions that explore cannibalization effects theoretically are [Feenstra and Ma \(2008\)](#), [Eckel and Neary \(2010\)](#), and [Dhingra \(2013\)](#). In contrast to these theoretical studies, we develop a structural model that can be used to provide quantitative evidence on how important it is to introduce such cannibalization effects into models of firm behavior.

Most existing empirical research on multiproduct firms has measured products using production classification codes (e.g., around 1,500 five-digit Standard Industrial Classification [SIC] categories in [Bernard, Redding, and Schott 2010](#)) or trade classification codes (e.g., around 10,000 Harmonized System codes in [Bernard, Jensen, and Schott 2009](#)). In contrast, we measure products at a much finer level of resolution using what we call “barcodes”—either 12-digit Universal Product Codes (UPCs) or 13-digit European Article Numbers (EANs)—in scanner data.⁶ This measure corresponds closely to the level at which product choice decisions are made by firms, because it is rare for an observable change in product attributes to occur without the introduction of a new barcode.

Our econometric approach builds on the literature estimating elasticities of substitution and quantifying the contribution of new varieties to welfare following [Feenstra \(1994\)](#) and [Broda and Weinstein \(2006, 2010\)](#). We extend this estimation approach to

which aggregate statistics such as the trade share and trade elasticity are sufficient statistics for welfare.

6. Recently, the 12-digit UPCs have been upgraded to 13-digit EAN-13s (European Article Numbers). The extra digit allows for more products and firms.

allow firms to be of positive measure relative to the market and to supply multiple products, which introduces variable markups and cannibalization effects. We show how this extended approach can be used to recover demand heterogeneity, marginal cost heterogeneity, variable markups, and cannibalization effects from the data. More generally, although other studies have used scanner data, such as [Chevalier, Kashyap, and Rossi \(2003\)](#), so far these data have not been used to estimate a structural model of heterogeneous multiproduct firms and quantify the sources of dispersion in firm sales.

III. DATA

Our data source is the Nielsen HomeScan database, which enables us to observe price and sales information for millions of products with a barcode.⁷ Barcode data have a number of advantages for the purpose of our analysis. First, since barcodes are inexpensive but provide sellers access to stores with scanners as well as Internet sales, producers have a strong incentive to purchase barcodes for all products that have more than a trivial amount of sales.⁸ This feature of the data means that it is likely we observe all products supplied by firms. Second, since assigning more than one product to a single barcode can interfere with a store's inventory system and pricing policy, firms have a strong incentive not to reuse barcodes. This second feature of the data ensures that identical goods do not have different barcodes.⁹ Thus, a barcode is the closest thing we have empirically to the theoretical concept of a good. Finally, since the cutoff size for a firm is to make a sale rather than an arbitrary number of workers, we actually observe something close to the full distribution of firms. We match barcodes to firms using the first few digits of the

7. Our results are calculated based on data from the Nielsen Company (US) and provided by the Marketing Data Center at the University of Chicago Booth School of Business. Information on availability and access to the data is available at <http://research.chicagobooth.edu/nielsen>.

8. GS1 provides a company with up to 10 barcodes for a \$250 initial membership fee and a \$50 annual fee. There are deep discounts in the per barcode cost for firms purchasing larger numbers of them (see <http://www.gs1us.org/get-started/im-new-to-gs1-us>).

9. For example, [Broda and Weinstein \(2010\)](#) compared barcodes with their product descriptions and found "no two identical UPCs with different product descriptions, or two different UPCs with the same product description" (p. 695).

barcode, which identify the company that owns the brand, for domestically produced and imported barcodes and for domestic and foreign companies.¹⁰

Nielsen collects its barcode data by providing handheld scanners to on average 55,000 households a year to scan each good purchased that has a barcode.¹¹ Prices are either downloaded from the store in which the good was purchased or hand entered, and the household records any deals used that may affect the price. These households represent a demographically balanced sample of households in 42 cities in the United States. Overall, the database covers around 30% of all expenditure on goods in the CPI.¹² We collapse the household dimension in the data and collapse the weekly purchase frequency to construct a national quarterly database by barcode on the total value sold, total quantity sold, and average price.¹³

Defining products as goods with barcodes has a number of advantages over defining goods by industry classifications. Whereas industry classifications aggregate products produced by a firm within an industry, our data reveal that large firms typically sell hundreds of different products within even a narrowly defined sector. In other words, while prior work equates multiproduct firms with multi-industry firms, our data hew

10. Firm prefixes are usually 7 digits, but they can be as long as 11 digits, so we use GS1 data to map the barcodes into firm identifiers. We could not obtain a firm identifier for just under 5% of the barcodes, and so we dropped these products. As an example of a firm identifier, for an imported spark plug, GS1 identifies the (potentially foreign) company that owns the brand (e.g., Bosch). If a barcode is made under license (e.g., Whole Foods contracts with Coca-Cola to manufacture a 12-ounce bottle of cola that is marketed under the Whole Foods brand), GS1 again identifies the company that owns the brand (in this example, Whole Foods).

11. The data for 2004 through 2006 come from a sample of 40,000 households, and the data for 2007 through 2011 come from a sample of 60,000 households.

12. For further discussion of the Nielsen data, see [Broda and Weinstein \(2010\)](#).

13. One question that naturally arises is whether it is appropriate to think of U.S. firms competing in a national market or in different regional markets. [Handbury and Weinstein \(2015\)](#) argue there is not that much heterogeneity in the price levels of barcoded goods across cities. Similarly, we find that national and regional expenditure shares and prices are strongly correlated in the data. National brands and firms (brands and firms that sell in 10 or more cities) account for 97% and 99% of expenditure, respectively, in cities with more than 1,000 households in the AC Nielsen data. Regressing the level of prices in these cities on national prices, quarter-year dummies, and barcode fixed effects, we find a partial R^2 (i.e., an R^2 not inclusive of the fixed effects) of 0.98. These results suggest that most of the variation in U.S. consumer prices reflects national shocks, not local ones.

extremely closely to what an economist would call a multiproduct firm. In principle, it could be appropriate to aggregate all output of a firm within an industry into a single good (Is whole milk the same as skim milk? Is a six-pack of soda the same as a two-liter bottle?). However, as we show theoretically, the validity of this procedure depends on the elasticity of substitution between the products supplied by a firm, which is an empirical question.

Instead of relying on product data for a single industry, we observe virtually the entire universe of goods purchased by households in the sectors that we examine. The database covers approximately 1.6 million goods purchased at some point by households in our sample. The data were weighted by Nielsen to correct for sampling error. For example, if the response rate for a particular demographic category is low relative to the census, Nielsen reweights the averages so that the price paid and the quantity purchased is representative of the United States as a whole.¹⁴

Nielsen organizes the barcodes into product groups according to where they would likely be stocked in a store. The 5 largest of our 98 product groups are carbonated beverages, pet food, paper products, bread and baked goods, and tobacco. We report a full list of the product groups in the [Online Appendix](#). Output units are common within a product group: typically volume, weight, area, length, or counts. Importantly, we deflate by the number of units in the barcode, so prices are expressed in price per unit (e.g., price per ounce). When the units are in counts, we also deflate by the number of goods in a multipack, so for instance, we would measure price per battery for batteries sold in multipacks. Although about two thirds of these barcoded items correspond to food items, the data also contain significant amounts of information about nonfood items like medications, housewares, detergents, and electronics.

[Table I](#) presents descriptive statistics for our sample of firms and barcodes in the 98 product groups. We weight the data by the sales of the product group in each quarter and average across product groups and quarters because sectors like carbonated

14. Although the barcode data include mostly final consumption products, available at retail stores, Section S9 of the [Online Appendix](#) reports the results of a robustness test in which we replicate our empirical procedure using Chilean international trade transactions data (which include both final consumption and intermediate products). We find a similar pattern of results using these international trade transactions data.

TABLE I
SAMPLE STATISTICS

	Mean	Median	Std. dev.	10th percentile	90th percentile	Max value
No. firms per product group	512	410	309	200	947	1,434
Firm sales	4,176	153	25,386	5	4,661	380,108
Log firm sales	12	12	3	8	15	19
No. of UPCs per firm	13	4	32	1	33	388
UPC sales	309	40	1,186	2	645	34,839

Notes. Weighted by product group–quarter sales. Firm and UPC sales in thousands. Calculations on data from the Nielsen Company (US) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

beverages are much larger economically than sectors like feminine hygiene. There are on average 512 firms in each product group with 90% of the product groups having more than 200 firms. We see enormous range in firm product scope. The median number of products supplied by a firm is 4 and the average is 13. On average, around 440,000 different UPCs were sold each quarter.

One of the most striking facts displayed in this table is the degree of firm heterogeneity. This is manifest in the skewness of the size and barcode distributions. The largest firm in an industry typically sells 2,500 times more than the median firm. We see similar patterns in terms of product scope and sales per product. The firm with the most products typically has 97 times more products than the firm with the median number of barcodes, and the barcode with the most sales on average generates almost 900 times more revenue than the revenue of the median barcode.

We see in [Table II](#) that almost 90% of sales in a product group was produced by firms with sales in the top decile of sales. [Table III](#) provides a more detailed description of this firm heterogeneity by focusing on the 10 largest firms in each product group (where we weight the averages by the sales of the product group). [Table III](#) reveals an almost fractal nature of firm sales. Around two thirds of all of the sales of firms in each product group is produced by the 10 largest firms (which on average only account for 2% of firms in each product group). While on average half of all output in a product group is produced by just five firms, 98% of firms have market shares of less than 2%. Thus, the typical sector is characterized by a few large firms and a competitive fringe composed of firms with trivial market shares. A second striking feature of the data is that

TABLE II
SIZE DISTRIBUTION BY DECILE

Ranked decile	Decile market share	Mean firm market share	Mean log firm sales	Avg. std. dev. log UPC sales	Mean no. UPCs per firm	Median no. UPCs per firm
1	87.72	2.69	16.4	1.8	68.1	44.9
2	7.09	0.22	14.5	1.6	26.0	21.0
3	2.69	0.08	13.5	1.6	14.7	11.8

5	0.63	0.02	12.0	1.4	5.8	4.6
6	0.32	0.01	11.4	1.3	4.0	3.2
7	0.17	0.00	10.7	1.2	2.8	2.2
8	0.08	0.00	9.9	1.1	2.1	1.5
9	0.03	0.00	8.9	0.9	1.5	1.1
10	0.01	0.00	7.3	0.6	1.2	1.0

Notes. Largest decile is ranked first. Weighted by product group–quarter sales. UPC counts and mean firm sales are across firm within each decile. Calculations on data from the Nielsen Company (US) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

TABLE III
SIZE DISTRIBUTION BY FIRM RANK

Firm rank	Firm market share (%)	Log firm sales	No. UPCs per firm
1	22.0	19.4	276.7
2	12.7	18.8	198.6
3	8.0	18.4	158.1
4	5.5	18.1	121.5
5	4.2	17.8	117.4
6	3.4	17.6	113.7
7	2.8	17.4	107.6
8	2.4	17.2	94.4
9	2.1	17.1	87.5
10	1.9	17.0	74.4

Notes. Largest firm is ranked first. Weighted by product group–quarter sales. Calculations on data from the Nielsen Company (US) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

even the largest firms are not close to being monopolists. The largest firm in a product group on average only has a market share of 22%. Finally, the data reveal that firms in the top decile of sales are all multiproduct firms, supplying on average 68 different goods with the largest firms supplying hundreds of goods.

The extent of multiproduct firms can be seen more clearly in Table IV, which shows the results of splitting the data by the

TABLE IV
 SIZE DISTRIBUTION BY NUMBER OF UPCs

No. of UPCs	No. of firms	Share of value (%)	Mean sales (thousands)	Median sales (thousands)	Avg. st. dev. UPC sales
1	160	0.8	72	63,871	
2–5	169	3.6	322	63,945	1.29
6–10	63	4.8	1,180	56,272	1.50
11–20	48	8.8	2,876	63,067	1.56
21–50	44	19.0	7,626	62,678	1.65
51–100	18	19.1	23,328	116,088	1.72
>100	10	43.8	109,999	122,045	1.79

Notes. Weighted by product group–quarter sales. To get last column, calculate standard deviation over log UPC sales by product group–quarter, then take weighted average across product group–quarters. Calculations on data from the Nielsen Company (US) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

number of UPCs supplied by a firm. Although single-product firms constitute about one third of all firms on average, these firms account for less than 1% of all output. In other words virtually all output is supplied by multiproduct firms. Moreover, the fact that over 90% of output is sold by firms selling 11 or more varieties and nearly two thirds of all output is supplied by firms selling more than 50 varieties suggests that single-product firms are more the exception than the rule.

Large firms not only sell more products but also a lot more of each product. The penultimate column of Table IV documents that while the typical barcode sold by a single-product firm brings in \$63,871 in revenue, the typical barcode sold by a firm selling over 100 barcodes brings almost twice as much (\$122,045). In other words, large firms not only supply more products, they sell more of each product. If firms differed only in the fixed cost of adding new varieties, one would not expect to see large firms sell more of each variety. The fact that they do strongly suggests that large firms must also differ in the marginal cost or demand for their output.

Finally, although the largest firms have nontrivial shares of particular product groups, these firms are small compared to the U.S. economy. Ninety-nine percent of firms in our sample have aggregate market shares (across all product groups) of less than 0.1% of total barcode sales. Even the largest firm only sells 3% of total barcode sales in our sample. Given that sales of packaged goods is only a fraction of total U.S. sales in all sectors, it is reasonable to conclude that no individual firm has the capacity to affect aggregate U.S. prices, expenditure, or welfare.

In sum, our overview of the data reveals some key features that we model in our empirical exercise. First, the vast majority of firms have trivial market shares, which means that if we believe that all firms may have some market power, we need to work with demand systems that do not imply that firms with trivial market shares have trivial markups. Second, the fact that most economic output is produced by multiproduct firms impels us to build this feature directly into the estimation system and allow for both differences in the fixed cost of developing new products as well as differences in marginal cost and demand across products. Third, the fact that there are firms with nontrivial market shares implies that at least some firms are likely to have market power. To the extent that these large firms internalize the effects of their price choices on market aggregates, this concentration of market shares will induce departures from the monopolistic competition benchmark. Finally, the fact that all the firms in our sample are small compared to the U.S. economy means that it is reasonable to assume that firms do not consider the implications of their pricing behavior on the aggregate economy.

IV. THEORETICAL FRAMEWORK

Our choice of functional forms is motivated by the data issues we identified already and by some theoretical concerns. Since much of the theoretical literature in international trade and economic geography has worked with CES models, we want our results to nest this case (at least within product groups), so that our results can be easily compared with existing work in trade, macro, and regional economics. However, we also need a framework that allows the elasticity of substitution for products supplied by the same firm to be different than that for products supplied by different firms, thereby allowing for the possibility of cannibalization effects. Finally, we need a setup that can be applied to firm-level data without imposing implausible assumptions or empirical predictions. This last requirement rules out two common demand systems: linear demand and the symmetric translog. A linear demand system would be problematic in our setting because one needs to impose the assumption that income elasticities are equal to zero and the estimation of marginal costs derived from a linear demand system can often result in negative values. While the symmetric translog demand system improves

on the linear demand system in this regard, it is a difficult system to implement at the firm level because it has the undesirable result that firms with negligible market shares have negligible markups.

Our estimation strategy therefore is based on an upper-level Cobb-Douglas demand system across product groups with CES nests below it. The upper-level Cobb-Douglas assumption implies that no firm has an incentive to try to manipulate prices in one product group to influence behavior in another product group. The reason is that each firm is assumed to be small relative to the aggregate economy (and hence cannot affect aggregate expenditure) and product group expenditure shares are determined by parameters alone. Therefore the firm problem becomes separable by product group.¹⁵ However, the nested CES structure within broadly defined product groups allows for strategic interactions among firms supplying similar products. Within this structure the real consumption of each product group is composed of the real consumption of each firm's output, which itself is made up of the consumption of each of the varieties supplied by the firm.

IV.A. Demand

To implement this approach, we assume that utility, \mathcal{U}_t , at time t is a Cobb-Douglas aggregate of real consumption, C_{gt}^G , of a continuum of product groups:¹⁶

$$\ln \mathcal{U}_t = \int_{g \in \Omega^G} \varphi_{gt}^G \ln C_{gt}^G dg, \quad \int_{g \in \Omega^G} \varphi_{gt}^G dg = 1,$$

where g denotes each product group, φ_{gt}^G is the share of expenditure on product group g at time t , and Ω^G is the set of product

15. In Section S5 of the [Online Appendix](#), we show how our approach can be extended to allow for a CES upper tier of utility, in which case firms have an incentive to price strategically across product groups. We focus on the Cobb-Douglas case in our baseline specification, because we find that product group expenditure shares are relatively constant over time despite changes in product group price indexes, which suggests that this specification provides a reasonable approximation to the data.

16. We use the superscripts G , F , and U to denote product group variables, firm variables, and UPC variables, respectively. Time is indexed by the subscript t . We use the subscripts g , f , and u to index individual product groups, firms, and UPCs, respectively, which belong to the sets Ω^G , Ω_{gt}^F , and Ω_{igt}^U , respectively, where the set of product groups Ω^G is constant over time. For example, C_{gt}^G is the product group consumption index for product group $g \in \Omega^G$, and σ_g^U is the elasticity of substitution across UPCs within product group $g \in \Omega^G$.

groups. Within product groups, we assume two CES nests for firms and UPCs. The first nest for firms enables us to connect with the existing literature on measuring firm productivity. The second nest for UPCs enables us to incorporate multiproduct firms. Therefore the consumption indexes for product groups (C_{gt}^G) and firms (C_{fgt}^F) can be written as, respectively:

$$(1) \quad C_{gt}^G = \left[\sum_{f \in \Omega_{gt}^F} \left(\varphi_{fgt}^F C_{fgt}^F \right)^{\frac{\sigma_g^F - 1}{\sigma_g^F}} \right]^{\frac{\sigma_g^F}{\sigma_g^F - 1}}, \quad C_{fgt}^F = \left[\sum_{u \in \Omega_{fgt}^U} \left(\varphi_{ut}^U C_{ut}^U \right)^{\frac{\sigma_g^U - 1}{\sigma_g^U}} \right]^{\frac{\sigma_g^U}{\sigma_g^U - 1}}.$$

In other words, the real consumption in any product group, g , is a function of the consumption of each firm f 's output, C_{fgt}^F , weighted by the consumer appeal of that firm's output, $\varphi_{fgt}^F > 0$, and adjusted for the substitutability of the output of each firm, $\sigma_g^F > 1$, where the set of active firms is Ω_{gt}^F .¹⁷ Similarly, the substitutability derived from the consumption of a firm f 's output within product group g , C_{fgt}^F , is a function of the consumption of each UPC (barcode) u , C_{ut}^U , multiplied by the consumer appeal of that barcode's output, $\varphi_{ut}^U > 0$, and adjusted by the substitutability between the various UPCs supplied by the firm, σ_g^U , where the set of these UPCs is Ω_{fgt}^U .¹⁸

There are a few features of this specification that are worth noting. First, if the elasticity of substitution across varieties supplied by a firm, σ_g^U , is finite, then the real output of a multiproduct firm is not equal to the sum of the outputs of each product. For example, if the only reason firms differ in size is that larger firms supply more varieties than do smaller firms, then assuming firm

17. We allow firms to be active in multiple product groups and firm appeal (φ_{fgt}^F) to vary across product groups g . Empirically, we find firm appeal to be strongly positively correlated across product groups within firms.

18. Our definition of appeal is utility per common physical unit (e.g., utility per ounce of a firm's output). However, variation in appeal could be interpreted either as a difference in utility per physical unit or as variation in the number of identical unobservable subunits within a physical unit. For example, it is isomorphic to say that Firm A produces products with twice the utility per ounce as Firm B and to say that half an ounce of Firm A's product generates as much utility as an ounce of Firm B's product. In the latter case, an ounce of Firm A's product would contain two "half-ounce subunits." We think our interpretation of utility per physical unit is the most natural for our data.

real output is the sum of the output of each variety will tend to understate the relative size of larger firms. This size bias is a topic that we explore in more detail later. Second, for much of what follows, we are focused on the sales decomposition within a given product group (g), so for notational simplicity we can suppress the g subscript on σ_g^F and σ_g^U until we need it again to pool results across sectors in Section IV.F. Third, we would expect (but do not impose) that the elasticity of substitution across varieties is larger within firms than across firms, that is, $\sigma^U \geq \sigma^F$. When the two elasticities are equal, our system will collapse to a standard CES at the product-group level, and if the inequality is strict, we will show that our setup features cannibalization effects. Although our nested CES specification provides a parsimonious and natural approach to modeling multiproduct firms, we consider the robustness of our results to alternative specifications in Section VII.

Fourth, we allow firms to be large relative to product groups (and hence internalize their effects on the consumption and price index for the product group). But we assume a continuum of product groups so that each firm is of measure zero relative to the economy as a whole (and hence takes aggregate expenditure E_t as given). When we take the model to the data, we approximate the continuum of product groups in the model with a large number of product groups in the data, in which each firm is small relative to aggregate expenditure, as discussed in Section III. Finally, since the utility function is homogeneous of degree 1 in firm appeal, it is impossible to define firm appeal, φ_{fgt}^F , independently of the product appeal of the varieties produced by that firm, φ_{ut}^U . We therefore need to choose a normalization. It will prove convenient to normalize the geometric means of the φ_{fgt}^F for each product group and the φ_{ut}^U for each firm to equal 1:

$$(2) \quad \tilde{\varphi}_{gt}^F = \left(\prod_{f \in \Omega_{gt}^F} \varphi_{fgt}^F \right)^{\frac{1}{N_{gt}^F}} = 1, \quad \tilde{\varphi}_{fgt}^U = \left(\prod_{u \in \Omega_{fgt}^U} \varphi_{ut}^U \right)^{\frac{1}{N_{fgt}^U}} = 1,$$

where N_{gt}^F is the number of firms in product group g at time t (the number of elements in Ω_{gt}^F) and N_{fgt}^U is the number of UPCs supplied by firm f within product group g at time t (the number of elements in Ω_{fgt}^U). Under this normalization, firm appeal (φ_{fgt}^F) affects the sales of all products supplied by firm f within

product group g proportionately, whereas product appeal (φ_{ut}^U) determines the relative sales of individual products u within firm f and product group g .¹⁹

We can gain some intuition for this framework by using the product group “carbonated beverages” as an example. Aggregate utility depends on the expenditure share (given by φ_{gt}^G) and amount of consumption of goods in the carbonated-beverages product group (given by C_{gt}^G). The utility derived from the consumption of carbonated beverages depends on the appeal of Coke versus Perrier (φ_{fgt}^F), the amounts of each firm’s real output consumed (C_{fgt}^F), and the degree of substitutability between Coke and Perrier (σ^F). Finally, the real amount of Coke or Perrier consumed (C_{fgt}^F) depends on the number of different types of soda produced by each company (N_{fgt}^U), the demand for each of these types of soda (φ_{ut}^U), the consumption of each variety of soda (C_{ut}^U), and how similar varieties of Coke (or Perrier) products are with other varieties offered by the same company (σ^U).

The corresponding exact price indexes for consumption are:

$$(3) \quad P_{gt}^G = \left[\sum_{f \in \Omega_{gt}^F} \left(\frac{P_{fgt}^F}{\varphi_{fgt}^F} \right)^{1-\sigma^F} \right]^{\frac{1}{1-\sigma^F}}, \quad P_{fgt}^F = \left[\sum_{u \in \Omega_{fgt}^U} \left(\frac{P_{kt}^U}{\varphi_{kt}^U} \right)^{1-\sigma^U} \right]^{\frac{1}{1-\sigma^U}},$$

where P_{gt}^G is the product group price index for product group g at time t , P_{fgt}^F is the firm price index for firm f and product group g at time t , and P_{ut}^U is the price of UPC u at time t .

Using the properties of CES demand, the expenditure share of firm f within product group g (S_{fgt}^F for $f \in \Omega_{gt}^F$) equals the elasticity of the product group price index with respect to the price index for firm f . Similarly, the expenditure share of product u

19. We find identical results with other normalizations. For example, we considered the alternative normalization of setting firm appeal to 1 for all firms ($\hat{\varphi}_{fgt}^F = 1$), in which case all variation in expenditure that is not explained by prices or the number of varieties is captured by product appeal ($\hat{\varphi}_{ut}^U$). In this alternative specification, product appeal is identical up to scale to a combination of firm and product appeal in our baseline specification: $(\hat{\varphi}_{ut}^U)^{\sigma^U - 1} = (\varphi_{ut}^U)^{\sigma^U - 1} (\varphi_{fgt}^F)^{\sigma^F - 1}$. We find that most of the variation in firm sales in this alternative specification is explained by the component of product appeal that is common to products within firms (firm appeal in our baseline specification).

within firm f (S_{ut}^U for $u \in \Omega_{fgt}^U$) equals the elasticity of the firm price index with respect to the price of product u :

$$(4) \quad S_{fgt}^F = \frac{\left(\frac{P_{fgt}^F}{\varphi_{fgt}^F}\right)^{1-\sigma^F}}{\sum_{k \in \Omega_{fgt}^F} \left(\frac{P_{kgt}^F}{\varphi_{kgt}^F}\right)^{1-\sigma^F}} = \frac{\partial P_{fgt}^G}{\partial P_{fgt}^F} \frac{P_{fgt}^F}{P_{fgt}^G}, \quad S_{ut}^U = \frac{\left(\frac{P_{ut}^U}{\varphi_{ut}^U}\right)^{1-\sigma^U}}{\sum_{k \in \Omega_{fgt}^U} \left(\frac{P_{kt}^U}{\varphi_{kt}^U}\right)^{1-\sigma^U}} = \frac{\partial P_{fgt}^F}{\partial P_{ut}^U} \frac{P_{ut}^U}{P_{fgt}^F}.$$

Equation (4) makes clear exactly how we conceive of firm and product appeal in this setup. Holding fixed prices, a UPC with more appeal has a larger market share. Similarly, holding fixed prices, firms that supply goods with more appeal have larger market shares.

The role of firm and product appeal can be seen by writing down the demand for the output of UPC u supplied by firm f within product group g :

$$(5) \quad C_{ut}^U = \left(\varphi_{fgt}^F\right)^{\sigma^F-1} \left(\varphi_{ut}^U\right)^{\sigma^U-1} E_{gt}^G \left(P_{gt}^G\right)^{\sigma^F-1} \left(P_{fgt}^F\right)^{\sigma^U-\sigma^F} \left(P_{ut}^U\right)^{-\sigma^U},$$

where E_{gt}^G denotes product group expenditure for product group $g \in \Omega^G$. Equation (5) is critical in determining how we can use this framework for understanding the different roles played by cost and appeal for the sales of a firm. While appeal affects consumption independently of price, cost only affects consumption through price.

IV.B. Technology

We allow the costs of supplying products to the market to vary across UPCs and firms. This specification encompasses both heterogeneity in productivity across firms (as in Melitz 2003) and heterogeneity in productivity within firms (as in Bernard, Redding, and Schott 2011). All costs are incurred in terms of a composite factor input that is chosen as our numéraire. We assume that the variable cost function is separable across UPCs and that supplying Y_{ut}^U units of output of UPC u incurs a total variable cost of $A_{ut}(Y_{ut}^U) = a_{ut}(Y_{ut}^U)^{1+\delta_g}$, where a_{ut} is a cost shifter and δ_g parameterizes the elasticity of marginal costs with respect to output. In addition, each firm f faces a fixed market entry cost for each product group of $H_{gt}^F > 0$ (e.g., the

fixed costs of supplying the market) and a fixed market entry cost for each UPC supplied of $H_{gt}^U > 0$ (e.g., the fixed costs of product development and distribution). We allow for entry and exit of both firms and products, where for the data to be an equilibrium of the model, it must be the case that no firm can profitably enter or exit and no product can be profitably added or dropped. To simplify notation, we again suppress the product group subscript g on δ_g until Section IV.F.

IV.C. Profit Maximization

In our baseline specification, we assume that firms choose prices under Bertrand competition, though we also report results in which firms instead choose quantities under Cournot competition. Since each firm is small relative to the aggregate economy and the upper tier of utility is Cobb-Douglas, the firm's problem is separable by product group.²⁰ With CES preferences within product groups, the decisions of any one firm only affect the decisions of other firms within that product group through the product group price index (P_{gt}^G). Each firm f within product group g chooses its set of UPCs $u \in \{\underline{u}_{fgt}, \dots, \bar{u}_{fgt}\}$ and their prices $\{P_{ut}^U\}$ for the final consumer to maximize its profits, taking into account these effects on the product group price index:²¹

$$(6) \quad \max_{\{\underline{u}_{fgt}, \dots, \bar{u}_{fgt}\}, \{P_{ut}^U\}} \Pi_{fgt}^F = \sum_{k=\underline{u}_{fgt}}^{\bar{u}_{fgt}} [P_{kt}^U Y_{kt}^U - A_{kt}(Y_{kt}^U)] - N_{fgt}^U H_{gt}^U - H_{gt}^F,$$

subject to the constraint that in equilibrium output of each UPC equals consumption ($Y_{kt}^U = C_{kt}^U$, where C_{kt}^U is determined by equation (5)); we index the UPCs supplied by the firm within the product group from the largest (\underline{u}_{fgt}) to the smallest

20. In Section S5 of the [Online Appendix](#), we discuss an extension to a CES upper tier of utility, in which firms price strategically across product groups. Given the recursive nature of our estimation strategy, this extension leaves our UPC and firm parameter estimates and the decomposition of firm sales into firm appeal, product scope, and prices unchanged, but alters the decomposition of prices into markups and costs (because the markup formula changes).

21. We follow existing research on heterogeneous firms in thinking of firms choosing prices faced by the final consumer. In Section S6 of the [Online Appendix](#), we show that our empirical approach allows for separate production and retail sector markups (we show how these markups difference out from our moment conditions), and we show how the model can be extended to incorporate a simple explicit retail sector.

(\bar{u}_{fgt}) in sales; and the total number of goods supplied by the firm within the product group is denoted by N_{fgt}^U , where $\bar{u}_{fgt} = \underline{u}_{fgt} + N_{fgt}^U$.

Multiproduct firms that are large relative to the market internalize the effects of their decisions for any one variety on the sales of their other varieties. From the first-order conditions for profit maximization, we can derive the firm markup for each UPC, as shown in [Appendix A](#):

$$(7) \quad \mu_{fgt}^F = \frac{\varepsilon_{fgt}^F}{\varepsilon_{fgt}^F - 1},$$

where we define the firm's perceived elasticity of demand as

$$(8) \quad \varepsilon_{fgt}^F = \sigma^F - (\sigma^F - 1)S_{fgt}^F = \sigma^F \left(1 - S_{fgt}^F\right) + S_{fgt}^F,$$

and the firm's pricing rule as

$$(9) \quad P_{ut}^U = \mu_{fgt}^F \gamma_{ut}, \quad \gamma_{ut} = (1 + \delta)a_{ut} (Y_{ut}^U)^\delta,$$

where γ_{ut} denotes marginal cost.

One of the surprising features of this setup is that markups only vary at the firm level within product groups. This is a generic property of nested demand systems, including nested translog, as shown in Sections S2 and S3 of the [Online Appendix](#). The intuition is that the firm internalizes that it is the monopoly supplier of its real output within the product group, which in our model equals real consumption of the firm's bundle of goods, C_{fgt}^F . Hence its profit maximization problem can be thought of in two stages. First, the firm chooses the price index (P_{fgt}^F) to maximize the profits from supplying real consumption (C_{fgt}^F), which implies a markup at the firm level within product groups over the cost of supplying real output. Second, the firm chooses the price of each UPC to minimize the cost of supplying real output within the product group (C_{fgt}^F), which requires setting the relative prices of UPCs equal to their relative marginal costs. Together these results ensure the same markup across all UPCs supplied by the firm within a given product group. Nonetheless, markups vary across product groups within firms ($\mu_{fgt}^F \neq \mu_{fmt}^F$ for $g \neq m$).²²

22. Section S4 of the [Online Appendix](#) shows how the model can be extended to incorporate another CES nest (product groups, firms, brands, and UPCs). Under

Although consumers have constant elasticity of substitution preferences (σ^F), each firm internalizes the effect of its pricing decisions on market price indexes, and hence perceives a variable elasticity of demand for UPC u (ε_{fgt}^F) that is decreasing in the expenditure share of the firm f supplying that UPC within product group g (S_{fgt}^F), as in [Atkeson and Burstein \(2008\)](#) and [Edmond, Midrigan, and Xu \(2015\)](#). As a result, the firm's equilibrium pricing rule ([equation \(9\)](#)) involves a variable markup (μ_{fgt}^F) that is increasing in its expenditure share within the product group (S_{fgt}^F). For a positive equilibrium price ([equation \(9\)](#)), we require that the perceived elasticity of demand (ε_{fgt}^F) is greater than 1 (firms produce substitutes), which requires the elasticity of substitution between firms (σ^F) to be sufficiently large. As a firm's sales become small relative to the product group ($S_{fgt}^F \rightarrow 0$), the markup ([equation \(7\)](#)) collapses to the standard constant markup of price over marginal cost under monopolistic competition and nested CES preferences (see [Allanson and Montagna 2005](#); [Arkolakis and Muendler 2010](#)).

Using the equilibrium pricing rule, profits for UPC u supplied by firm f (Π_{ut}^U) are equal to variable profits ($\pi_{ut}^U(N_{fgt}^U)$) minus fixed costs. UPC variable profits in turn can be written in terms of UPC revenues ($P_{ut}^U Y_{ut}^U$), the markup (μ_{fgt}^F), and the elasticity of costs with respect to output (ζ_{ut}):

$$(10) \quad \Pi_{ut}^U = \pi_{ut}^U(N_{fgt}^U) - H_{gt}^U,$$

$$(11) \quad \pi_{ut}^U(N_{fgt}^U) = P_{ut}^U Y_{ut}^U - A_{ut}(Y_{ut}^U) = \left(\frac{\zeta_{ut} \mu_{fgt}^F - 1}{\zeta_{ut} \mu_{fgt}^F} \right) P_{ut}^U Y_{ut}^U,$$

$$\text{where } \zeta_{ut} = \frac{dA_{ut}(Y_{ut}^U)}{dY_{ut}^U} \frac{Y_{ut}^U}{A_{ut}(Y_{ut}^U)} = 1 + \delta.$$

That is, $\pi_{ut}^U(N_{fgt}^U)$ denotes the variable profits from UPC u when firm f supplies N_{fgt}^U UPCs within product group g .

the assumption that prices are chosen separately by brand, this extension can generate variation in markups across brands within a given firm and product group.

IV.D. *Cannibalization Effects*

The number of UPCs supplied by each firm f within product group g , N_{fgt}^U , is determined by the requirement that the increase in profits from introducing an additional UPC, $\bar{u}_{fgt} + 1$, minus the reduction in profits from reduced sales of existing UPCs $u \in \{\underline{u}_{fgt}, \dots, \bar{u}_{fgt}\}$ is less than the fixed cost of introducing the new UPC, H_{fgt}^U . If a firm supplies N_{fgt}^U products in equilibrium, then it must be the case that if it were to introduce a new good, its profits would fall, that is,

$$\sum_{u=\underline{u}_{fgt}}^{\bar{u}_{fgt}+1} \pi_{ut}^U(N_{fgt}^U + 1) - (N_{fgt}^U + 1)H_{fgt}^U < \sum_{u=\underline{u}_{fgt}}^{\bar{u}_{fgt}} \pi_{ut}^U(N_{fgt}^U) - N_{fgt}^U H_{fgt}^U$$

$$(12) \iff \pi_{\bar{u}_{fgt}+1,t}^U(N_{fgt}^U + 1) - \sum_{u=\underline{u}_{fgt}}^{\bar{u}_{fgt}} \left\{ \pi_{ut}^U(N_{fgt}^U) - \pi_{ut}^U(N_{fgt}^U + 1) \right\} < H_{fgt}^U.$$

In the case where the number of UPCs is large and can be approximated by a continuous variable, we obtain after some manipulation (see Appendix B) the following measure of cannibalization:

$$(13) \quad -\frac{\partial Y_{ut}^U}{\partial N_{fgt}^U} \frac{N_{fgt}^U}{Y_{ut}^U} = \left[\left(\frac{\sigma^U - \sigma^F}{\sigma^U - 1} \right) + \left(\frac{\sigma^F - 1}{\sigma^U - 1} \right) S_{fgt}^F \right] S_{N_{fgt}^U}^U N_{fgt}^U > 0, \text{ for } \sigma^U \geq \sigma^F > 1,$$

where $S_{N_{fgt}^U}^U$ is the share of the new UPC in expenditure on the firm within the product group and S_{fgt}^F is the share of the firm in expenditure within the product group. This measure of cannibalization is the partial elasticity of the sales of existing products with respect to the number of products. This partial elasticity captures the direct effect of the introduction of a new product on the sales of existing products, through the firm and product group price indexes, holding constant the prices and marginal costs of these existing products. This partial elasticity with respect to number of products is expressed in terms of observed expenditure shares, and takes the same value under both price and quantity competition, as shown in the Appendix.

The first term on the right-hand side captures cannibalization within firms: the introduction of a UPC reduces the firm price index (P_{fgt}^F), which reduces the revenue of existing UPCs if varieties are more substitutable within firms than across firms

($\sigma^U > \sigma^F$). The second term captures cannibalization across firms: The introduction of the new UPC reduces the product-group price index (P_{gt}^C), which reduces the revenue of existing UPCs if varieties are more substitutable within product-groups than across product-groups ($\sigma^F > 1$).

There are two useful benchmarks for understanding the magnitude of cannibalization. In both cases, it is useful to think of the introduction of a standardized product that has a market share equal to the average market share of the firm's other goods within the product group ($S_{N_{fgt}^U}^U N_{fgt}^U = 1$). We define the "cannibalization rate" as the value of the partial elasticity (equation (13)) for such a standardized product. At one extreme, suppose that firms are monopolistic competitors, $S_{fgt}^F \approx 0$, and all products supplied by a firm are as differentiated among themselves as they are with the output of other firms, that is, $\sigma^U = \sigma^F$. In this case, the cannibalization rate is zero, because all sales revenue arising from introducing a new product comes from the sales of goods supplied by other firms. Thus, a world with monopolistic competition and equal product differentiation is a world with no cannibalization. Clearly, the cannibalization rate will rise if firms cease being small $S_{fgt}^F > 0$ or if goods supplied by the same firm are more substitutable with each other than with goods supplied by different firms: $\sigma^U > \sigma^F$. At the other extreme, suppose that goods are "perfect substitutes" within firms, that is, $\sigma^U = \infty > \sigma^F$, so that varieties are differentiated across firms but there is no difference between varieties supplied by the same firm. In this case, the cannibalization rate is 1, because any sales of a new product are exactly offset by a reduction in the sales of existing products. Thus the cannibalization rate provides a measure of where in the spectrum ranging from perfect substitutes to equal differentiation the output of a firm lies.

IV.E. The Sources of Firm Heterogeneity

In this section, we use the model to quantify the contribution of the different sources of firm heterogeneity to the dispersion in sales across firms. Nominal sales of firm f within product group g , E_{fgt}^F , is the sum of sales across UPCs supplied by the firm:

$$E_{fgt}^F \equiv \sum_{u \in \Omega_{fgt}^U} P_{ut}^U C_{ut}^U.$$

Using CES demand (equation (5)), firm sales can be rewritten as:

$$(14) \quad E_{fgt}^F = (\varphi_{fgt}^F)^{\sigma^F - 1} E_{gt}^G (P_{gt}^G)^{\sigma^F - 1} (P_{fgt}^F)^{\sigma^U - \sigma^F} \sum_{u \in \Omega_{fgt}^U} \left(\frac{P_{ut}^U}{\varphi_{ut}^U} \right)^{1 - \sigma^U}.$$

Using the firm price index (equation (3)) to substitute for $P_{fgt}^{\sigma^U - \sigma^F}$, dividing and multiplying by $(N_{fgt}^U)^{\frac{\sigma^F - 1}{\sigma^U - 1}}$, and taking logarithms, we obtain:

$$(15) \quad \begin{aligned} \ln E_{fgt}^F &= \ln E_{gt}^G + (\sigma^F - 1) \ln P_{gt}^G + (\sigma^F - 1) \ln \varphi_{fgt}^F + \left(\frac{\sigma^F - 1}{\sigma^U - 1} \right) \ln N_{fgt}^U \\ &+ \left(\frac{\sigma^F - 1}{\sigma^U - 1} \right) \ln \left(\frac{1}{N_{fgt}^U} \sum_{u \in \Omega_{fgt}^U} \left(\frac{P_{ut}^U}{\varphi_{ut}^U} \right)^{1 - \sigma^U} \right), \end{aligned}$$

which decomposes the variation in firm sales into contributions of product group variables (E_{gt}^G and P_{gt}^G), firm appeal (φ_{fgt}^F), product scope (N_{fgt}^U), and average product-appeal-adjusted prices (final term). This decomposition holds regardless of assumptions made about firm pricing behavior and markups (e.g., Bertrand versus Cournot pricing or the introduction of retail markups), because it uses the observed prices paid by consumers (P_{ut}^U).

Using the equilibrium pricing rule (equation (9)), the final term can be further decomposed into the contributions of the geometric mean of marginal costs ($\tilde{\gamma}_{fgt}$), relative appeal-adjusted marginal costs across UPCs $\left(\frac{\left(\frac{\gamma_{ut}}{\tilde{\gamma}_{fgt}} \right)}{\varphi_{ut}^U} \right)$, and the firm markup (μ_{fgt}^F):

$$(16) \quad \begin{aligned} \ln E_{fgt}^F &= \left\{ \ln E_{gt}^G + (\sigma^F - 1) \ln P_{gt}^G \right\} \\ &+ \left\{ (\sigma^F - 1) \ln \varphi_{fgt}^F + \left(\frac{\sigma^F - 1}{\sigma^U - 1} \right) \ln N_{fgt}^U \right\} \\ &+ \left\{ [-(\sigma^F - 1) \ln \tilde{\gamma}_{fgt}] + \left(\frac{\sigma^F - 1}{\sigma^U - 1} \right) \ln \left(\frac{1}{N_{fgt}^U} \sum_{u \in \Omega_{fgt}^U} \left(\frac{\left(\frac{\gamma_{ut}}{\tilde{\gamma}_{fgt}} \right)}{\varphi_{ut}^U} \right)^{1 - \sigma^U} \right) \right\} - (\sigma^F - 1) \ln \mu_{fgt}^F, \end{aligned}$$

where $\tilde{\gamma}_{fgt} = \left(\prod_{u \in \Omega_{fgt}^U} \gamma_{ut} \right)^{\frac{1}{N_{fgt}^U}}$; recall that $\gamma_{ut} = (1 + \delta) a_{ut} (Y_{ut}^U)^\delta$ denotes marginal cost.

Equation (16) decomposes firm sales into seven terms that capture the various margins through which firms can differ in sales. Clearly these margins are related to one another, since both the number of products and the markup are endogenous to firm appeal, product appeal, and marginal cost. Nonetheless, the decomposition (16) isolates the direct effects of firm appeal, product appeal, and marginal cost from their indirect effects through the number of products and the markup.

Although our decomposition is exact for any comovement in variables, it is easiest to obtain intuition for this equation if we consider one-at-a-time, small movements in each variable so that we can safely ignore interactions between different variables. We therefore explain the intuition for this equation in terms of small movements in each variable, and note that in general and in our empirical implementation we allow all variables to move simultaneously.

The seven terms in equation (16) can be grouped into four main elements. The first element, in the first set of braces, captures market size and relative pricing. Our demand system is homogeneous of degree 1 in product group expenditures, so firm sales rise one to one with aggregate expenditures. The second term in the first set of braces captures the impact of the product group price index that summarizes the prices of competing varieties. Holding fixed a firm's characteristics, an increase in the product group price level of 1% will cause the firm's sales to rise by $(\sigma^F - 1)\%$. Here, the elasticity of substitution between the firm's output and the output of other firms, σ^F , plays the crucial role of determining how much a relative price movement affects firm sales.

"Total firm appeal" is captured by the second two terms in braces, which capture the impacts of "firm appeal," φ_{fgt}^F , and the number of products the firm offers, "product scope," N_{fgt}^U . Consider two firms that supply the same number of products, but one firm supplies varieties that consumers prefer (measured in utility per unit), meaning that $\varphi_{fgt}^F > \varphi_{f'gt}^F$ and $N_{fgt}^U = N_{f'gt}^U$. Firm f will then have higher sales; how much depends on the elasticity of substitution between firm output, σ^F . For a larger value of this

elasticity, a given difference in firm appeal will translate into a larger difference in firm sales.

Now consider two firms that supply products with identical appeal, but one firm supplies more UPCs than another ($N_{fgt}^U > N_{f'gt}^U$). Here, it is easiest to think about this term in a symmetric world in which all goods and firms have identical appeal ($\varphi_{ut}^U = \varphi_{ft}^F = 1$ for all $u \in \Omega_{fgt}^U$ and $f \in \Omega_{gt}^F$) and identical marginal cost ($\gamma_{ut} = \gamma_t$ for all $u \in \Omega_{fgt}^U$ and $f \in \Omega_{gt}^F$), so we can just focus on the role played by product scope. Although firms have identical appeal, they do not have identical market shares because they differ in the number of products they offer, that is, $\ln N_{fgt}^U > \ln N_{f'gt}^U$. For example, if consumers treated all UPCs identically regardless of which firm supplied them, $\sigma^U = \sigma^F$, firm f would sell $\ln\left(\frac{N_{fgt}^U}{N_{f'gt}^U}\right)\%$ more output than firm f' . More generally, if the products supplied by a firm are more substitutable with each other than with those of other firms, $\sigma^U > \sigma^F$, the percentage gain in sales accruing to a firm that adds a product will be less than 1, reflecting the fact that a new product will cannibalize the sales of its existing products. Indeed, the degree of cannibalization will depend on the magnitude of σ^U ; as this elasticity approaches infinity, the cannibalization rate will approach 1, and all sales of new products will come from the sales of the firm's existing products. Hence, in this limiting case of $\sigma^U \rightarrow \infty$, adding product scope will have no impact on sales.

The terms in the third set of braces capture the role played by marginal costs. These costs can be divided into average marginal cost ($\tilde{\gamma}_{fgt}$) and "cost dispersion." Average marginal costs ($\tilde{\gamma}_{fgt}$) is the more conventional measure that captures the fact that high-cost firms have lower sales in equilibrium. The second term captures the fact that a firm sells more in equilibrium as the *dispersion* in the cost-to-appeal ratio across its products increases. The intuition is straightforward. The term in logs is a form of Theil index of dispersion with the numerator being the cost of production of each variety relative to the average and the denominator being the product appeal relative to the average (which is always normalized to 1). Consider a firm that supplies N_{fgt}^U identical varieties at identical cost so that $\varphi_{ut} = \gamma_{ut} = \tilde{\gamma}_{fgt} = 1$ for all $u \in \Omega_{fgt}^U$. In this case, the cost dispersion term will be 0 because there is no

dispersion in appeal or marginal cost among the firm's products. Now consider a comparative static in which we multiply γ_{ut} by $\tau > 1$ and divide γ_{kt} for all $k \neq u$ by $\tau^{\frac{1}{(\sigma_g^U - 1)}}$. This change has the property of keeping geometric mean marginal costs, $\tilde{\gamma}_{fgt}$, equal to 1 while increasing the dispersion in the cost of providing each element of the production bundle. Even though geometric mean marginal costs are unaffected by construction, firm sales will rise because the increase in dispersion allows the firm to supply its production bundle more cheaply by shifting its output toward the sales of cheaper varieties. This cost-dispersion term indicates that a firm sells more if its cost-to-appeal ratio is less evenly distributed across its varieties. Here, we also see the first instance of the insidiousness of demand for understanding multiproduct firms—in the nested CES case, one cannot express firm-level marginal costs without reference to the demand parameters σ^F and σ^U .

Finally, the last term captures the role played by firm markups (μ_{fgt}^F), which are themselves a function of the elasticity of substitution between firms (σ^F) and firm market share (S_{fgt}^F).

IV.F. Firm Sales Decompositions

While the decomposition given in equation (16) is exact for each sector, it is difficult to use that specification to understand the general determinants of firm size because aggregate product group expenditures are a major determinant of firm sales. Therefore we decompose firm sales in each product group relative to the geometric mean for that product group:

$$\begin{aligned} \Delta^g \ln E_{fgt}^F &= \left\{ (\sigma_g^F - 1) \Delta^g \ln \varphi_{fgt}^F + \left(\frac{\sigma_g^F - 1}{\sigma_g^U - 1} \right) \Delta^g \ln N_{fgt}^U \right\} \\ &+ \left\{ \left[-(\sigma_g^F - 1) \Delta^g \ln \tilde{\gamma}_{fgt} \right] + \left(\frac{\sigma_g^F - 1}{\sigma_g^U - 1} \right) \Delta^g \ln \left(\frac{1}{N_{fgt}^U} \sum_{u \in \Omega_{fgt}^U} \left(\frac{\gamma_{ut}}{\varphi_{ut}^U} \right)^{1 - \sigma_g^U} \right) \right\} \\ (17) \quad & - (\sigma_g^F - 1) \Delta^g \ln \mu_{fgt}^F, \end{aligned}$$

where we have reintroduced the product group subscript g for all the relevant variables, and Δ^g is the difference operator relative to the geometric mean for product group g , such that

$$\Delta^g \ln E_{fgt}^F = \left[\ln E_{fgt}^F - \frac{1}{N_{fgt}^F} \sum_{k \in \Omega_{fgt}^F} \ln E_{kgt}^F \right].$$

The left-hand side of [equation \(17\)](#) is the sales of firm f relative to average firm sales in the sector, and the five terms on the right-hand side tell us the importance of relative firm appeal, scope, average marginal costs, cost dispersion, and markups in understanding cross-sectional differences in firm size. Moreover, we can also undertake this decomposition for a firm's sales growth rate by taking the first difference of [equation \(17\)](#) over time, which in our notation simply involves replacing Δ^g in [equation \(17\)](#) with $\Delta^{g,t}$, where $\Delta^{g,t}$ is the double difference operator relative to the geometric mean for product group g and over time t , so that

$$\Delta^{g,t} \ln E_{fgt}^F = \left[\ln E_{fgt}^F - \frac{1}{N_{gt}^F} \sum_{k \in \Omega_{gt}^F} \ln E_{kgt}^F \right] - \left[\ln E_{fgt-1}^F - \frac{1}{N_{gt-1}^F} \sum_{k \in \Omega_{gt-1}^F} \ln E_{kgt-1}^F \right].$$

We can decompose the cross-sectional variation in firm sales using a procedure analogous to [Eaton, Kortum, and Kramarz's \(2004\)](#) variance decomposition commonly used in the international trade literature. In particular, we regress each of the components of log firm sales in the decomposition (17) on log firm sales as follows:

$$(18) \quad (\sigma_g^F - 1) \Delta^g \ln \varphi_{fgt}^F = \alpha_g^\varphi \Delta^g \ln E_{fgt}^F + \varepsilon_{fgt}^\varphi,$$

$$(19) \quad -(\sigma_g^F - 1) \Delta^g \ln \tilde{\gamma}_{fgt} = \alpha_g^\gamma \Delta^g \ln E_{fgt}^F + \varepsilon_{fgt}^\gamma,$$

$$(20) \quad \left(\frac{\sigma_g^F - 1}{\sigma_g^U - 1} \right) \Delta^g \ln \left[\frac{1}{N_{fgt}^U} \sum_{u \in \Omega_{fgt}^U} \left(\frac{\gamma_{ut}}{\varphi_{ut}} \right)^{1-\sigma^U} \right] = \alpha_g^D \Delta^g \ln E_{fgt}^F + \varepsilon_{fgt}^D,$$

$$(21) \quad \left(\frac{\sigma_g^F - 1}{\sigma_g^U - 1} \right) \Delta^g \ln N_{fgt}^U = \alpha_g^N \Delta^g \ln E_{fgt}^F + \varepsilon_{fgt}^N,$$

$$(22) \quad -(\sigma_g^F - 1) \Delta^g \ln \mu_{fgt}^F = \alpha_g^\mu \Delta^g \ln E_{fgt}^F + \varepsilon_{fgt}^\mu,$$

where we have again differenced relative to the geometric mean for the product group. We allow the coefficients $\{\alpha_g^\varphi, \alpha_g^\gamma, \alpha_g^D, \alpha_g^N, \alpha_g^\mu\}$ to differ across product groups. By the properties of

OLS, this decomposition allocates the covariance terms between the components of firm sales equally across those components, and implies $\alpha_g^\varphi + \alpha_g^\gamma + \alpha_g^D + \alpha_g^N + \alpha_g^\mu = 1$. The values for each of the α 's provide us with a measure of how much of the variation in firm sales can be attributed to each component. If we replace Δ^g with $\Delta^{g,t}$ in these equations, we can determine how much of the variance in firm sales growth rates can be attributed to each component. Thus, estimation of these five equations provides us with a simple way to decompose firm sales in the cross section and in the time series.

IV.G. Decomposing Changes in Firm Average Appeal

When decomposing firm growth, we can go one step further and understand how much of a firm's change in appeal is due to the introduction of new products and how much is due to changes in the appeal of existing products. Note that our normalization for UPC appeal implies that the geometric mean of the φ_{ut}^U equals one for each firm f within each product group g in each period t , that is,

$$(23) \quad \varphi_{fgt}^F = \varphi_{fgt}^F \left(\prod_{u \in \Omega_{fgt}^U} \varphi_{ut}^U \right)^{\frac{1}{N_{fgt}^U}}.$$

We can then take log differences of this equation relative to the mean within a product group and over time to yield:

$$(24) \quad \begin{aligned} \Delta^{g,t} \ln \varphi_{fgt}^F &\equiv \Delta^t \ln \varphi_{fgt}^F - \Delta^t \overline{\ln \varphi_{fgt}^F} = \Delta^t \ln \varphi_{fgt}^F + \frac{1}{N_{fgt}^U} \sum_{u \in \Omega_{fgt}^U} \ln \varphi_{ut}^U \\ &\quad - \frac{1}{N_{fg,t-1}^U} \sum_{u \in \Omega_{fg,t-1}^U} \ln \varphi_{u,t-1}^U - \Delta^t \overline{\ln \varphi_{fgt}^F}, \end{aligned}$$

where Δ^t denotes the first difference operator over time such that $\Delta^t \ln \varphi_{fgt}^F = \ln \varphi_{fgt}^F - \ln \varphi_{fg,t-1}^F$; a bar above a variable denotes a mean such that $\overline{\ln \varphi_{fgt}^F} = \frac{1}{N_{fgt}^F} \sum_{f \in \Omega_{fgt}^F} \ln \varphi_{fgt}^F$; and our normalization of

product appeal to have a geometric mean of 1 implies that the second and third terms are both equal to 0.

To isolate the sources of changes in firm average appeal, we distinguish between UPCs that are supplied in both periods versus those that are supplied in only one of the two periods.

Let $I_{fgt}^U = \Omega_{fgt}^U \cap \Omega_{fgt-1}^U$ denote the set of UPC's that are supplied by firm f within product group g in both periods t and $t - 1$. Similarly, define I_{fgt}^{U+} to be the set of newly introduced UPCs, that is, the set of UPCs in Ω_{fgt}^U but not in Ω_{fgt-1}^U , and I_{fgt}^{U-} to be the set of disappearing UPCs, that is, the set of UPCs in Ω_{fgt-1}^U but not in Ω_{fgt}^U .

Noting that $|\Omega_{fgt}^U| = |I_{fgt}^U| + |I_{fgt}^{U+}|$ and $|\Omega_{fgt-1}^U| = |I_{fgt}^U| + |I_{fgt}^{U-}|$, we can decompose the change in firm average appeal into changes in appeal for a constant set of products and changes in appeal from the adding and dropping of UPCs:

$$\begin{aligned} \Delta^{g,t} \ln \varphi_{fgt}^F = & \left\{ \frac{|I_{fgt}^U|}{|\Omega_{fgt}^U|} \left[\frac{1}{|I_{fgt}^U|} \sum_{u \in I_{fgt}^U} \ln \varphi_{ut}^U \right] - \frac{|I_{fgt}^U|}{|\Omega_{fgt-1}^U|} \left[\frac{1}{|I_{fgt}^U|} \sum_{u \in I_{fgt}^U} \ln \varphi_{ut-1}^U \right] + \left(\Delta^t \ln \varphi_{fgt}^F - \Delta^t \overline{\ln \varphi_{fgt}^F} \right) \right\} \\ & + \left\{ \frac{|I_{fgt}^{U+}|}{|\Omega_{fgt}^U|} \left[\frac{1}{|I_{fgt}^{U+}|} \sum_{u \in I_{fgt}^{U+}} \ln \varphi_{ut}^U \right] - \frac{|I_{fgt}^{U-}|}{|\Omega_{fgt-1}^U|} \left[\frac{1}{|I_{fgt}^{U-}|} \sum_{u \in I_{fgt}^{U-}} \ln \varphi_{ut-1}^U \right] \right\}. \end{aligned} \tag{25}$$

The first term in braces captures changes in appeal for a constant set of products and includes the change in firm average appeal ($\Delta^t \ln \varphi_{fgt}^F$), as well as the difference between average product appeal for the common set of products (in square brackets) weighted by their relative importance in the set of products in each quarter. This difference adjusts changes in our measure of firm appeal for changes in our normalization due to the entry and exit of new goods. We refer to the first term in braces in [equation \(25\)](#) as the “demand effect.” It represents the change in the appeal of the UPCs present in both periods. If the firm does not add or eliminate any products, the summation terms will be 0 since our normalization means that average log product appeal must be 0 in all periods.

However, if the set of products changes, the summation terms will not necessarily be 0. Product turnover can influence sales through product upgrading, which is measured in the second term in braces in [equation \(25\)](#), as well as through changes in the number of products, which enters separately into the decomposition of log firms sales in [equation \(17\)](#). The “product-upgrading effect” (the second term in braces in [equation \(25\)](#)) captures changes in appeal from the adding and dropping of products. Product upgrading depends on average product appeal for the entering and exiting products (in square brackets) weighted

by their relative importance in the set of products in each quarter. For example, suppose a firm introduces a new high-appeal product and retires a low-appeal product leaving the number of products unchanged. In this case, the second term in braces will be positive, reflecting the fact that the firm upgraded the average appeal of its product mix.

V. STRUCTURAL ESTIMATION

Our structural estimation of the model has two components. First, given data on expenditure shares and prices $\{S_{ut}^U, S_{fgt}^F, P_{ut}^U\}$ and known values of the model parameters $\{\sigma_g^U, \sigma_g^F, \delta_g\}$, we show how the model can be used to determine unique values of firm appeal (φ_{fgt}^F), product appeal (φ_{ut}^U), and marginal cost shocks (a_{ut}) up to our normalization of appeal. These correspond to structural residuals of the model that are functions of the observed data and parameters and ensure that the model exactly replicates the observed data. We use these structural residuals to implement our decomposition of firm sales from Section IV.E with our observed data on expenditure shares and prices.

Second, we estimate the model parameters $\{\sigma_g^U, \sigma_g^F, \delta_g\}$ using a generalization of Feenstra (1994) and Broda and Weinstein (2006, 2010) to allow firms to be large relative to the markets in which they operate (which introduces variable markups) and to incorporate multiproduct firms (so that firm pricing decisions are made jointly for all varieties). This estimation uses moment conditions in the double-differenced structural residuals $\{\varphi_{ft}^F, \varphi_{ut}^U, a_{ut}\}$ and also has a recursive structure. In a first step, we estimate the elasticity of substitution across UPCs within firms and the marginal cost elasticity for each product group $\{\sigma_g^U, \delta_g\}$. In a second step, we use these estimates for UPCs to estimate the elasticity of substitution across firms for each product group $\{\sigma_g^F\}$.

V.A. Structural Residuals

We begin by showing that there is a one-to-one mapping from the observed data on expenditure shares and prices $\{S_{ut}^U, S_{fgt}^F, P_{ut}^U\}$ and the model's parameters $\{\sigma_g^U, \sigma_g^F, \delta_g\}$ to the unobserved structural residuals $\{\varphi_{ut}^U, \varphi_{fgt}^F, a_{ut}\}$.

Given known values for the model's parameters $\{\sigma_g^U, \sigma_g^F, \delta_g\}$ and the observed UPC expenditure shares and prices, we can use the expression for the expenditure share given in equation (4) to determine UPC appeal $\{\varphi_{ut}^U\}$ up to our normalization that the geometric mean of UPC appeal is equal to 1. These solutions for UPC appeal and observed UPC prices can be substituted into the CES price index (equation (3)) to compute firm price indexes $\{P_{fgt}^F\}$. These solutions for firm price indexes and observed firm expenditure shares can be combined with the CES expenditure share (4) to determine firm appeal $\{\varphi_{fgt}^F\}$ up to our normalization that the geometric mean of firm appeal is equal to 1. Furthermore observed firm expenditure shares and the CES markup (7) are sufficient to recover firm markups $\{\mu_{fgt}^F\}$. These solutions for markups and observed UPC prices and expenditures can be substituted into the CES pricing rule (equation (9)) to determine the marginal cost shock $\{a_{ut}\}$.

Finally, our solutions for markups and observed UPC expenditures can be combined with CES variable profits (equation (11)) to obtain upper bounds to the fixed costs of supplying UPCs (H_{gt}^U) and the fixed costs of supplying the market (H_{gt}^F). The upper bound for UPC fixed costs for each product group (H_{gt}^U) is defined by the requirement that variable profits for the least profitable UPC within a product group must be greater than this fixed cost. Similarly, the upper bound for firm fixed costs for each product group (H_{gt}^F) is defined by the requirement that variable profits for the least profitable firm must be greater than this fixed cost.

This mapping from the observed data on expenditure shares and prices $\{S_{ut}^U, S_{fgt}^F, P_{ut}^U\}$ and the model's parameters $\{\sigma_g^U, \sigma_g^F, \delta_g\}$ to the unobserved structural residuals $\{\varphi_{ut}^U, \varphi_{fgt}^F, a_{ut}\}$ does not impose assumptions about the functional forms of the distributions for the structural residuals or about their correlation with one another. When we estimate the model's parameters $\{\sigma_g^U, \sigma_g^F, \delta_g\}$, we impose some identifying assumptions on the double-differenced values of these structural results but not on their levels. Therefore, having recovered these structural residuals, we can examine the relationship between them.

V.B. UPC Moment Conditions

We now discuss our methodology for estimating the elasticities of substitution $\{\sigma_g^U, \sigma_g^F\}$ and the elasticity of marginal costs

with respect to output $\{\delta_g\}$, which uses moment conditions in double-differenced values of the structural residuals $\{\varphi_{fgt}^F, \varphi_{ut}^U, a_{ut}\}$. This estimation again has a recursive structure. In a first step, we estimate the elasticity of substitution across UPCs within firms for each product group $\{\sigma_g^U\}$ and the marginal cost elasticity $\{\delta_g\}$. In a second step, we use these estimates for UPCs to estimate the elasticity of substitution across firms for each product group $\{\sigma_g^F\}$.

In the first step, we double-difference log UPC expenditure shares (equation (4)) over time and relative to the largest UPC within each firm to obtain the following equation for relative UPC demand:

$$(26) \quad \Delta^{\underline{u},t} \ln S_{ut}^U = (1 - \sigma_g^U) \Delta^{\underline{u},t} \ln P_{ut}^U + \omega_{ut},$$

where u is a UPC supplied by the firm; \underline{u} corresponds to the largest UPC supplied by the same firm (as measured by the sum of expenditure across the two quarters); $\Delta^{\underline{u},t}$ is the double-difference operator across UPCs and over time such that $\Delta^{\underline{u},t} \ln S_{ut}^U = \Delta^t S_{ut}^U - \Delta^t S_{\underline{u}t}^U$; Δ^t is the first-difference operator over time such that $\Delta^t \ln S_{ut}^U = S_{ut}^U - S_{ut-1}^U$; and $\omega_{ut} = (\sigma_g^U - 1) [\Delta^t \ln \varphi_{ut}^U - \Delta^t \ln \varphi_{\underline{u}t}^U]$ is a stochastic error. We can compute this double difference for all firms that have two or more UPCs and are present for two or more consecutive time periods.

Double-differencing the UPC pricing rule (equation (9)) enables us to obtain an equation for relative UPC supply. Using the cost function $(A_{ut}(Y_{ut}^U) = a_{ut}(Y_{ut}^U)^{1+\delta})$ and noting that $Y_{ut}^U = \frac{E_{ut}^U}{P_{ut}^U} = \frac{E_{fgt}^F S_{ut}^U}{P_{ut}^U}$, the UPC pricing rule given in equation (9) can be rewritten as:

$$P_{ut}^U = \mu_{fgt}^F \gamma_{ut} = \left(\mu_{fgt}^F\right)^{\frac{1}{1+\delta_g}} (1 + \delta_g)^{\frac{1}{1+\delta_g}} a_{ut}^{\frac{1}{1+\delta_g}} \left(E_{fgt}^F\right)^{\frac{\delta_g}{1+\delta_g}} \left(S_{ut}^U\right)^{\frac{\delta_g}{1+\delta_g}}.$$

Taking logs and double-differencing, we obtain the following equation for relative UPC supply:

$$(27) \quad \Delta^{\underline{u},t} \ln P_{ut}^U = \frac{\delta_g}{1 + \delta_g} \Delta^{\underline{u},t} \ln S_{ut}^U + \kappa_{ut},$$

where the markup (μ_{fgt}^F) and total firm expenditure (E_{fgt}^F) have differenced out because they take the same value across UPCs within the firm; and $\kappa_{ut} = \frac{1}{1+\delta_g} [\Delta^t \ln a_{ut} - \Delta^t \ln a_{\underline{u}t}]$ is a stochastic

error. Since the firm markup differences out and we observe prices, our estimation approach is the same under either price or quantity competition and thus is robust across these different forms of competition.

Following Broda and Weinstein (2006), the orthogonality of the double-differenced demand and supply shocks defines a set of moment conditions (one for each UPC):

$$(28) \quad G(\beta_g) = \mathbb{E}_{\mathbb{T}}[v_{ut}(\beta_g)] = 0,$$

where $\beta_g = \begin{pmatrix} \sigma_g^U \\ \delta_g \end{pmatrix}$; $v_{ut} = \omega_{ut}\kappa_{ut}$; and $\mathbb{E}_{\mathbb{T}}$ is the expectations operator over time. For each product group, we stack all the moment conditions to form the GMM objective function and obtain:

$$(29) \quad \hat{\beta}_g = \arg \min_{\beta_g} \{G^*(\beta_g)'WG^*(\beta_g)\} \quad \forall g,$$

where $G^*(\beta_g)$ is the sample analog of $G(\beta_g)$ stacked over all UPCs in a product group and W is a positive definite weighting matrix. As in Broda and Weinstein (2010), we weight the data for each UPC by the number of raw buyers for that UPC to ensure that our objective function is more sensitive to UPCs purchased by larger numbers of consumers. We impose the theoretical restriction that $\sigma_g^U, \sigma_g^F > 0$, which is a necessary (though not sufficient) condition for positive markups. We do not impose the theoretical restrictions that $\sigma_g^U > \sigma_g^F > 1$ and instead check whether these inequalities are satisfied by our estimates. We also do not restrict δ_g .

The moment condition (equation (28)) for each UPC involves the expectation of the product of the double-differenced demand and supply shocks: $v = \omega_{ut}\kappa_{ut}$. From relative demand (equation (26)) and relative supply (equation (27)), this expectation depends on the variance of prices, the variance of expenditure shares, the covariance of prices and expenditure shares, and parameters. Our identifying assumption that this expectation is equal to 0 defines a rectangular hyperbola in (σ_g^U, δ_g) space for each UPC within a product group g , along which a higher value of σ_g^U has to be offset by a lower value of δ_g for the expectation to be equal to 0 (Leontief 1929). Therefore, this rectangular hyperbola places bounds on the demand and supply elasticities for each UPC within that product group, even in the absence of instruments for demand and supply. Furthermore, if the variances

for the double-differenced demand and supply shocks are heteroskedastic across UPCs, the rectangular hyperbolas are different for each pair of UPCs within the product group, and their intersection can be used to separately identify the demand and supply elasticities for that product group (Feenstra 1994). Consistent with these identifying assumptions, we find that the double-differenced demand and supply shocks are in general heteroskedastic.²³

Our assumption that the double-differenced demand and supply shocks are orthogonal follows a standard approach in the international trade and macroeconomics literatures (see in particular Feenstra 1994; Broda and Weinstein 2006, 2010). This double differencing is important in addressing most standard endogeneity concerns. For example, a standard concern is that there may be firm-level shocks (e.g., changes in management) that affect both costs and appeal (quality or taste) across all products. Differencing across products within firms eliminates such common firm-level shocks. Another standard concern is that products may have different production technologies, which could affect both costs and appeal (quality or taste) in all time periods. Differencing over time within products eliminates such time-invariant heterogeneity between products. Therefore our double differencing nets out both these types of shocks. In other words, our identification is based only on *relative* differences in demand and supply of individual barcodes.

The second main potential threat to identification is a change in observable product characteristics that affects both relative costs and relative appeal, but this endogeneity concern is not present in barcode data. Fortunately, any substantive change in product characteristics is accompanied by the introduction of a new barcode.²⁴ Therefore, by using variation within barcodes over time, we hold constant observable product characteristics. As a result, it is much harder to think of reasons double-differenced changes in production costs that leave the observable characteristics of a product constant should affect double-differenced consumer demand for that product conditional on

23. In a White test for heteroskedasticity, we are able to reject the null hypothesis of homoskedasticity at conventional significance levels for 94% of product groups.

24. Minor changes like the style of product label do not result in new barcodes, but retailers and manufacturers do not use the same barcodes for different products because doing so would interfere with their inventory management.

price. We provide further evidence in support of these identifying assumptions and the robustness of our results in Section VII.

V.C. Firm Moment Conditions

We use our estimates of the UPC elasticities of substitution $\{\sigma_g^U\}$ from the first step to solve for UPC appeal $\{\varphi_{ut}^U\}$ and compute the firm price indexes $\{P_{fgt}^F\}$ using equations (3) and (4). In our second step, we double difference log firm expenditure shares (4) over time and relative to the largest firm within each product group, \underline{f} , to obtain the following equation for relative firm market share:

$$(30) \quad \Delta^{f,t} \ln S_{fgt}^F = (1 - \sigma_g^F) \Delta^{f,t} \ln P_{fgt}^F + \omega_{fgt},$$

where $\Delta^{f,t}$ is the double difference operator across firms within a product group and over time such that $\Delta^{f,t} \ln S_{fgt}^F = \Delta^t \ln S_{fgt}^F - \Delta^t \ln S_{\underline{f}gt}^F$ and the stochastic error is $\omega_{fgt} \equiv (\sigma_g^F - 1) \Delta^{f,t} \ln \varphi_{fgt}^F$.

Estimating equation (30) using OLS could be problematic because changes in firm price indexes could be correlated with changes in firm appeal: $\text{Cov}(\Delta^{f,t} \ln P_{fgt}^F, \Delta^{f,t} \ln \varphi_{fgt}^F) \neq 0$. To find a suitable instrument for changes in firm price indexes, we use the structure of the model to write changes in firm price indexes in terms of the underlying UPC characteristics of the firm. Using the CES expenditure shares (equation (4)), we can write relative UPC expenditures in terms of relative UPC prices and relative UPC demand shifters:

$$(31) \quad \frac{S_{ut}^U}{\tilde{S}_{fgt}^U} = \left(\frac{\frac{P_{ut}^U}{\varphi_{ut}^U}}{\frac{\tilde{P}_{fgt}^U}{\varphi_{fgt}^U}} \right)^{1-\sigma_g^U}, \quad u \in \Omega_{fgt}^U,$$

where here we compare each UPC to the geometric mean of UPCs within the firm and product group, which is denoted by a tilde above a variable so that, for example, $\tilde{S}_{fgt}^U = \exp \left\{ \frac{1}{N_{fgt}^U} \sum_{u \in \Omega_{fgt}^U} \ln S_{ut}^U \right\}$. Using this expression for relative expenditure shares to substitute for product appeal (φ_{ut}^U) in the CES

price index (equation (3)), we can write the firm price index solely in terms of observed relative expenditures and the geometric mean of UPC prices:

$$(32) \quad \ln P_{fgt}^F = \ln \tilde{P}_{fgt}^U + \frac{1}{1 - \sigma_g^U} \ln \left[\sum_{u \in \Omega_{fgt}^U} \frac{S_{ut}^U}{\tilde{S}_{fgt}^U} \right],$$

where we have used our normalization that $\tilde{\varphi}_{fgt}^U = 1$.

Equation (32) decomposes the firm price index into two terms. The first term is entirely conventional: the geometric mean of the prices of all goods supplied by the firm. When researchers approximate this firm price index using firm-level unit values or the prices of representative goods supplied by firms, they are essentially capturing this component of the firm price index. The second term is novel and arises because the conventional price indexes are not appropriate for multiproduct firms. The log component of the second term is a variant of the Theil index of dispersion.²⁵ If the shares of all products are equal, the Theil index will equal $\ln N_{ft}^U$, which is increasing in the number of products supplied by the firm, N_{fgt}^U . Since the Theil index is multiplied by $(1 - \sigma_g^U)^{-1} \leq 0$, the firm's price index falls as the number of goods supplied by the firm rises. This Theil index also increases as the dispersion of the market shares across UPCs within the firm rises.

One can obtain some intuition for this formula by comparing it to the conventional price indexes commonly used in economics. Firm price indexes are typically constructed by making at least one of two critical assumptions—firms only supply one product ($N_{fgt}^U = 1$), or the goods supplied by firms are perfect substitutes (i.e., $\sigma_g^U = \infty$). Either of these assumptions is sufficient to guarantee that the firm's price level equals its average price level. However, both of these assumptions are likely violated in reality. The average price of a firm's output overstates the price level for multiproduct firms because consumers derive more utility per dollar spent on a firm's production if that production bundle contains more products. Thus, while the (geometric) average firm

25. The standard Theil index uses shares relative to simple average shares, while ours expresses shares relative to the geometric mean.

price is a theoretically rigorous way to measure the price level of firms that produce perfect substitutes, it overstates the prices of firms that produce differentiated goods, and this bias will tend to rise as the number of products supplied by the firm increases.

The structure of the model implies that the dispersion of the shares of UPCs in firm expenditure (S_{ut}^U) only affects the shares of firms in product group expenditure (S_{fgt}^F) through the firm price indexes (P_{fgt}^F). Double differencing [equation \(32\)](#) for the log firm price index over time and relative to the largest firm within each product-group, we obtain:

$$(33) \quad \Delta^{f,t} \ln P_{fgt}^F = \Delta^{f,t} \ln \tilde{P}_{fgt}^U + \frac{1}{1 - \sigma_g^U} \Delta^{f,t} \ln \left[\sum_{u \in \Omega_{fg}^U} \frac{S_{ut}^U}{\tilde{S}_{fgt}^U} \right],$$

where the model implies that the second term on the right-hand side containing the shares of UPCs in firm expenditure is a suitable instrument for the double-differenced firm price index in [equation \(30\)](#). We find that this instrument is powerful in the first-stage regression ([equation \(33\)](#)), with a first-stage F -statistic for the statistical significance of the excluded exogenous variable that is substantially above the recommended threshold of 10 from [Stock, Wright, and Yogo \(2002\)](#).

VI. ESTIMATION RESULTS

We present our results in several stages. First, we present the elasticity and appeal estimates and show that they are reasonable. Then we use these estimates to examine cannibalization. Finally we present results on the sources of firm heterogeneity.

VI.A. *Estimated Elasticities of Substitution*

Because we estimate 98 σ_g^U 's and σ_g^F 's, it would needlessly clutter the article to present all of them individually. [Table V](#) shows that goods supplied by the same firm are imperfect substitutes. For UPCs, the estimated elasticity of substitution ranges from 4.7 at the 95th percentile to 17.6 at the 5th percentile with a median elasticity of 6.9. These numbers are large compared with trade elasticities, reflecting the fact that products supplied by the

TABLE V
DISTRIBUTION OF 98 GMM ESTIMATES

Ranked percentile	σ_g^U	σ_g^F	$\sigma_g^U - \sigma_g^F$	δ_g
1	24.4	12.8	16.8	0.62
5	17.6	8.5	9.4	0.42
10	14.1	7.3	6.5	0.30
25	8.6	5.1	4.0	0.20
50	6.9	3.9	2.6	0.16
75	5.4	3.1	2.2	0.09
90	5.0	2.6	1.8	0.06
95	4.7	2.3	1.7	0.04
99	4.4	2.1	1.2	0.02

Notes. Percentiles are decreasing: largest estimate is ranked first. σ_g^U is the elasticity of substitution between barcodes sold by the same firm in a product group, σ_g^F is the elasticity of substitution between firms within a product group, and δ_g is the elasticity of marginal cost with respect to output for firms in a product group. Calculations on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

same firm are closer substitutes than products supplied by different firms. The median elasticity implies that a 1% price cut causes the sales of that UPC to rise by 6.9%.²⁶

A second striking feature of our results is that the elasticity of substitution among varieties supplied by a firm is always larger than that between firms (i.e., $\sigma_g^U > \sigma_g^F$). It is important to remember that this is not a result we imposed on the data. Moreover, most of the elasticities are precisely estimated—in 82% of the cases, we can statistically reject the hypothesis that $\sigma_g^U = \sigma_g^F$ at the 5% level. The higher elasticities of substitution across UPCs than across firms imply that varieties are more substitutable within firms than across firms, which implies cannibalization effects from the introduction of new varieties by firms. Moreover, the fact that the estimated elasticities of substitution are always greater than one implies that firms' varieties are substitutes, which is required for positive markups of price over marginal costs (cf. equation (9)).

26. The UPC own price elasticity derived in equation (38) is given by

$$\frac{\partial C_{ut}^U P_{ut}^U}{\partial P_{ut}^U C_{ut}^U} = (\sigma_g^F - 1) S_{ut}^F S_{ut}^U + (\sigma_g^U - \sigma_g^F) S_{ut}^U - \sigma_g^U.$$

To assess whether our elasticities are plausible, it is useful to compare our estimates with those of other papers. To do this, we restricted ourselves to comparing our results with studies that used U.S. scanner data and estimated elasticities for the same product groups as ours. We do this because, as Broda and Weinstein (2006) show, elasticity estimates for aggregate data can look quite different than those for disaggregate data. Unfortunately, we did not find studies estimating the elasticity of substitution within firms, but we did find studies that examined elasticities that can be compared with our cross-firm elasticity, σ_g^F . Gordon, Goldfarb, and Li (2013) and the literature review therein presents results for comparable product groups using quite different estimation methodologies. For the 12 overlapping product groups, we find similar results with an average estimated elasticity of 3.65 compared to 3.14 in Gordon, Goldfarb, and Li (2013) (a difference of around 14%), as reported in further detail in Section S10 of the Online Appendix.²⁷ Therefore, although our empirical approach has a number of novel features in modeling multiproduct firms that are of positive measure relative to the markets in which they operate, the empirical estimates generated by our procedure are reasonable compared to the benchmark of findings from other empirical studies.

VI.B. Firm and Product Appeal

Firm and product appeal are a second key component of our decomposition. Our estimation procedure allows us to estimate a different ϕ_{ut}^U for every quarter in our data set. We have strong priors that product appeal should be fairly stable across time. One way to gauge this stability is to regress these variables on UPC fixed effects to determine how much of a product's appeal is common across time periods. When we do this and include time fixed effects to control for inflation and other common demand shocks, we find that the R^2 is 0.84, which implies that very little of the variation in our measures of appeal arises from changes in appeal within UPCs over time. We should also expect firm appeal, ϕ_{igt}^F , to exhibit a strong firm component.

27. The product categories are butter and margarine, carbonated soft drinks, coffee, deodorant, ketchup, laundry detergent, mayonnaise, mustard, peanut butter, spaghetti sauce, toilet paper, and yogurt.

Running an analogous regression for firm appeal including firm and time fixed effects, we find that the R^2 is 0.83.²⁸

We can gain further intuition for the reasonableness of our estimates and the role played by the various sources of firm heterogeneity by computing some simple correlations. Our procedure for estimating the model's parameters $(\sigma_g^U, \sigma_g^F, \delta_g)$ assumes that the double-differenced product appeal $(\Delta^{u,t} \ln \varphi_{ut}^U)$ and cost shocks $(\Delta^{u,t} \ln a_{ut})$ are orthogonal to one another, where $\Delta^{u,t}$ denotes a double difference relative to the largest product within a firm and over time. But we do not impose restrictions on the relationship between the relative levels of sales $(\Delta^f \ln S_{ut}^U)$, prices $(\Delta^f \ln P_{ut}^U)$, appeal $(\Delta^f \ln \varphi_{ut}^U)$, and marginal costs $(\Delta^f \ln \gamma_{ut} = \Delta^f \ln ((1 + \delta_g) a_{ut} Y_{ut}^{\delta_g}))$, where Δ^f denotes a first difference relative to the geometric mean for the firm. In Table VI, we present the correlations between the relative levels of these variables across barcodes. There are several important insights from this table. First, relative barcode appeal $(\Delta^f \ln \varphi_{ut}^U)$ and relative marginal cost $(\Delta^f \ln \gamma_{ut}^U)$ are positively correlated. The fact that the correlation is 0.94 means that on average it is more costly for firms to produce more appealing products. This high correlation is not that surprising because much of the variation in appeal among a single firm's products probably reflects manufacturing differences (e.g., size and quality) that are reflected in marginal costs.

Table VI is also useful in understanding the determinants of barcode sales. While relative barcode appeal $(\Delta^f \ln \varphi_{ut}^U)$ is strongly correlated with relative barcode sales $(\Delta^f \ln E_{ut}^U)$, relative marginal cost $(\Delta^f \ln \gamma_{ut}^U)$ is not. How can it be that marginal costs are strongly associated with barcode appeal, which in turn is positively correlated with sales, but marginal costs are not correlated with sales? The answer can be garnered from rewriting our expenditure share equation (4) after log differencing:

$$(34) \quad \Delta^f \ln E_{ut}^U = (1 - \sigma_g^F) \Delta^f \ln \gamma_{ut} - (1 - \sigma_g^F) \Delta^f \ln \varphi_{ut}^U,$$

28. Most of the explanatory power in these regressions is contributed by the UPC and firm fixed effects. Running the same regressions without the time fixed effects, we continue to find R^2 of 0.84 and 0.83, respectively.

TABLE VI
SALES COMPONENT CORRELATIONS (UPC LEVEL)

	$\Delta^f \ln E_{ut}^U$	$\Delta^f \ln P_{ut}^U$	$\Delta^f \ln \varphi_{ut}^U$	$\Delta^f \ln \gamma_{ut}$
$\Delta^f \ln E_{ut}^U$	1.00			
$\Delta^f \ln P_{ut}^U$	0.03	1.00		
$\Delta^f \ln \varphi_{ut}^U$	0.36	0.94	1.00	
$\Delta^f \ln \gamma_{ut}$	0.03	1.00	0.94	1.00

Note: All correlations significant at the 0.1% level. $\Delta^f \ln E_{ut}^U$ is the log sales of each barcode less the log geometric mean sales of all barcodes sold by the firm. $\Delta^f \ln P_{ut}^U$ is the log price of each barcode less the log geometric mean price of all barcodes sold by the firm. $\Delta^f \ln \varphi_{ut}^U$ is the log appeal of each barcode. $\Delta^f \ln \gamma_{ut}$ is the log marginal cost of each barcode less the log geometric mean marginal cost of all barcodes sold by the firm. Calculations on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

where we have used the fact that $\Delta^f \ln E_{ut}^U = \Delta^f \ln S_{ut}^U$, $P_{ut}^U = \mu_{fgt}^F \gamma_{ut}$, and the markup μ_{fgt}^F is common across UPCs within firms and hence differences out.

From equation (34), there are two forces at work in these correlations. First, there is the direct effect of marginal costs on sales through the price channel, which is captured by the first term: higher marginal costs lead to higher prices and lower sales. However, we also saw that the correlation between appeal and marginal cost is positive, which arises from the fact that higher marginal costs are associated with higher appeal products, which tend to have higher sales. The fact that these forces tend to cancel explains why the correlation coefficients between sales and either marginal costs or appeal are much less than one. The reason that this attenuation matters more for marginal cost than appeal stems from the variance of the two variables. The variance of relative appeal is 16% larger than the variance of relative marginal cost.²⁹ In other words, appeal varies more than marginal costs, so the high covariance between the two variables cancels out the tendency of high cost products to have low market shares,

29. One can think of this issue in terms of the standard formula for omitted variable bias. If we estimate equation (34) and omit appeal, the regression coefficient on marginal cost $(1 - \sigma_g^F)$ will be biased upward by $\frac{(\sigma_g^F - 1) \text{cov}(\Delta^f \ln(\gamma_{ut}), \Delta^f \ln(\varphi_{ut}))}{\text{var}(\Delta^f \ln(\gamma_{ut}))}$. On the other hand, if we estimate the equation omitting marginal cost, the coefficient on appeal $(\sigma_g^F - 1)$ will be biased downward by $\frac{(\sigma_g^F - 1) \text{cov}(\Delta^f \ln(\varphi_{ut}), \Delta^f \ln(\gamma_{ut}))}{\text{var}(\Delta^f \ln(\varphi_{ut}))}$. The important point is that the biases in each regression just differ by the magnitude of the variances, but the true coefficients are of the same magnitude (but opposite sign). Thus, if the variance of appeal exceeds the variance of marginal cost, we are more likely to find no correlation between sales and marginal cost than between sales and appeal.

TABLE VII
SALES COMPONENT CORRELATIONS (FIRM LEVEL)

	$\Delta^g \ln E_{ft}^F$	$\Delta^g \ln P_{ft}^F$	$\Delta^g \ln \varphi_{ft}^F$	$\Delta^g \ln N_{ft}^U$	$\Delta^g \ln \tilde{\gamma}_{ft}$	$\Delta^g \ln CD_{ft}$	$\Delta^g \ln \mu_{ft}^F$
$\Delta^g \ln E_{ft}^F$	1.00						
$\Delta^g \ln P_{ft}^F$	-0.20	1.00					
$\Delta^g \ln \varphi_{ft}^F$	0.51	0.68	1.00				
$\Delta^g \ln N_{ft}^U$	0.79	-0.35	0.24	1.00			
$\Delta^g \ln \tilde{\gamma}_{ft}$	0.01	0.96	0.80	-0.10	1.00		
$\Delta^g \ln CD_{ft}$	0.64	-0.28	0.19	0.68	-0.07	1.00	
$\Delta^g \ln \mu_{ft}^F$	0.26	-0.07	0.15	0.23	-0.01	0.16	1.00

Notes. All correlations significant at the 0.1% level. The difference operator $\Delta^g \ln x_{ft}$ denotes the value of $\log x$ for firm f in quarter t , less the log geometric mean value of x among all firms in product group g that quarter. The variable x is one of the following: E_{ft}^F is firm sales, P_{ft}^F is the firm price index, φ_{ft}^F is firm appeal, N_{ft}^U is the number of products sold by a firm, $\tilde{\gamma}_{ft}^F$ is the average marginal cost among a firm's products, $CD_{ft} = \frac{1}{N_{ft}^U} \sum_{u \in \Omega_{ft}^U} \left(\frac{\mu_{ft}^F}{\varphi_{ft}^F} \right)^{1-\sigma_g^U}$ is the firm's cost dispersion, and μ_{ft}^F is the firm's markup.

but it does not fully negate the tendency of high appeal products to have high market shares.

Table VII shows that this pattern is even stronger at the firm level. Again we express each variable in logs and now take differences across firms relative to the geometric mean for the product group (denoted by the Δ^g operator). We find that firm appeal is still strongly positively correlated with firm average marginal costs ($\Delta^g \ln(\tilde{\gamma}_{fgt}^F)$), presumably because firm appeal is closely associated with manufacturing costs, but the magnitude of this correlation is lower than at the barcode level. This lower correlation may reflect the fact that appeal differences across firms are more reflective of taste differences than is the case for products made by the same firm. Here, too, firm appeal is positively correlated with firm sales, but there is no correlation between firm average marginal costs and firm sales. In the firm-level results, the stronger correlation between sales and appeal is driven by the fact that the variance of firm appeal is 60% larger than that of firm average marginal cost.

Table VII also indicates strong positive correlations between scope and sales and between cost dispersion and sales, which reflects the fact that larger firms tend to produce more goods.³⁰

30. Across products within firms, we find that large firms are characterized by more dispersion in product appeal. Regressing the coefficient of variation of log

Taking [Tables VI and VII](#) together, we find strong but imperfect correlations between appeal and prices at both the barcode and firm level. These correlations give some support to the work that uses price as a proxy for appeal or quality. Although there is a very strong link between price and quality for products produced by the same firm, there is a weaker but still substantial correlation between price and quality across firms. These results highlight the additional insights one can obtain by measuring appeal through the lens of our model. Finally, although markups are positively correlated with sales, they are, if anything, negatively correlated with firm price indexes. The reason is that although large firms have higher markups for each barcode, they produce so many more barcodes than small firms that their price index is lower.³¹

In sum, these correlations point to a number of ways in which our measures appear reasonable: cost, price, and appeal are all positively correlated at the barcode and firm level. In addition, appeal is less correlated with marginal costs across firms than across products within firms. Most important for what follows, the fact that appeal and scope are highly correlated with firm sales but average marginal cost is almost uncorrelated with it provides the intuition for why our decompositions are going to point to appeal and scope as being the principal drivers of firm heterogeneity.

VI.C. *Markups*

We use our estimated elasticities of substitution to compute implied firm markups, as summarized in [equations \(7\) and \(8\)](#). These markups vary along two dimensions. The first is cross-sector variation, which captures the fact that σ_g^F varies systematically across product groups, and the second is within-sector variation, which captures the fact that larger firms have higher

product appeal within firms on log firm sales, and controlling for the log number of products, we find a positive and statistically significant coefficient on log firm sales.

31. Our estimates of the components of firm sales can be related to the literature on the firm-size distribution (e.g., [Rossi-Hansberg and Wright 2007](#)). In line with existing results in that literature, we reject the null hypothesis of an untruncated Pareto distribution for firm sales (the relationship between log rank and log size is concave). Consistent with our finding that firm appeal is the most important determinant of firm size, we also reject the null hypothesis of an untruncated Pareto distribution for firm appeal (the relationship between log rank and log size is again concave).

markups within a sector than smaller firms. As discussed already, our procedure for estimating the elasticities $\{\sigma_g^U, \sigma_g^F\}$ is robust to the assumption of either price or quantity competition, because the firm markup differences out in [equation \(26\)](#) and we observe prices. However, the markup formula, and hence the decomposition of prices into markups and marginal cost, depends in an important way on the form of competition. In our baseline specification, we assume Bertrand competition in prices, but we report the derivation of the markup under Cournot competition in quantities in the [Appendix](#). A key takeaway from this comparison is that Cournot competition generates substantially higher markups for larger firms than Bertrand competition if goods are substitutes. Additionally, as shown in the Appendix, under Bertrand competition, the relative markups of firms depend solely on the distribution of market shares (and hence are robust to different estimates of the elasticity of substitution between firms). In contrast, under Cournot competition, the relative markups of firms depend on the distribution of market shares and the elasticity of substitution between firms.

[Table VIII](#) reports the distribution of markups across firms in our 98 product groups. The first column reports the percentile of the markup distribution; the second column reports the Cournot markup; the third column reports the Bertrand markup; the fourth column reports the markup implied by our parameter estimates under monopolistic competition across firms (based on σ^F); and the fifth column reports the markup implied by our parameter estimates under monopolistic competition across UPCs (based on σ^U). The median markup (under either Bertrand or Cournot) is 31%, which is slightly lower than the [Domowitz, Hubbard, and Petersen \(1988\)](#) estimate of 36% for U.S. consumer goods, and slightly above the median markups estimated by [De Loecker and Warzynski \(2012\)](#) for Slovenian data which range from 17% to 28%. This suggests that our markup estimates are reasonable in the sense that they do not differ greatly from those found in prior work.

Within product groups, the markups of most firms are essentially the same regardless of whether we assume firms compete through prices or quantities, because most firms have trivial market shares.³² In contrast, the markups of the largest firms

32. From the 1st to the 10th decile of the distribution of sales within product groups, the average Bertrand (Cournot) markup varies from 0.38 to 0.37 (0.40 to 0.37).

TABLE VIII
DISTRIBUTION OF MARKUPS

Ranked percentile	Cournot	Bertrand	Monopolistic competition (σ_g^F)	Monopolistic competition (σ_g^U)
10	0.57	0.57	0.52	0.24
25	0.45	0.45	0.45	0.23
50	0.31	0.31	0.31	0.16
75	0.24	0.24	0.24	0.14
90	0.16	0.16	0.16	0.09

Notes. Percentiles are decreasing; largest is ranked first. Markup=(Price – Marginal Cost)/Marginal Cost. The “Cournot” column presents markups computed assuming firms compete as Cournot competitors. The “Bertrand” column presents markups computed assuming firms compete as Bertrand competitors. “Monopolistic Competition (σ_g^F)” and “Monopolistic Competition (σ_g^U)” present markups constructed under the assumption that firms are monopolistic competitors with an elasticity of substitution of σ_g^F or σ_g^U , respectively. Calculations on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

TABLE IX
DISTRIBUTION OF LARGEST FIRMS’ MARKUPS RELATIVE TO PRODUCT GROUP AVERAGE

Ranked percentile	Cournot			Bertrand		
	Largest	Second	Third	Largest	Second	Third
10	4.36	2.61	1.81	1.72	1.29	1.14
25	2.97	1.73	1.46	1.41	1.18	1.11
50	1.94	1.50	1.30	1.24	1.13	1.08
75	1.55	1.33	1.23	1.16	1.09	1.06
90	1.36	1.23	1.16	1.10	1.07	1.05

Notes. Percentiles are decreasing; largest is ranked first. Markup=(Price – Marginal Cost)/Marginal Cost. The “Cournot” columns present markups computed assuming firms compete as Cournot competitors. The “Bertrand” columns present markups computed assuming firms compete as Bertrand competitors. Calculations on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

are substantially different. Table IX shows the distribution of the markups for the three largest firms by product group. In each case, we report the markup relative to the average markup in the product group, so that one can see how different the markup of the largest firm is. The median largest firm in a product group has a markup that is 24% larger than the average if we assume competition is Bertrand and almost double the average if we assume competition is Cournot. However, as one can also see from this table, these markups drop off quite rapidly for the second- and third-largest firms. Therefore, both modes of competition suggest that very few firms can exploit their market power.

VI.D. Cannibalization Rate

Our estimated elasticities of substitution also determine the magnitude of the cannibalization rate, defined as the partial elasticity of the sales of existing products with respect to the introduction of a standardized new product with a market share equal to the average market share of the firm's other goods ($S_{N_{igt}^U}^U N_{igt}^U = 1$ in equation (13)). As discussed already, a cannibalization rate of 0 corresponds to equal differentiation of a firm's products from its rivals and monopolistic competition, while a rate of 1 corresponds to a world in which products are perfect substitutes within firms. On average across product groups, we find a cannibalization rate for the median firm of around 0.50, which lies almost exactly between the benchmarks of perfect substitutes and equal differentiation. This cannibalization level implies that about half of the sales of a new product introduced by a firm comes from the sales of existing products and half from the sales of other firms. The fact that these cannibalization rates are much less than 1 underscores the fact that it is not appropriate to treat the goods supplied by a multiproduct firm as perfect substitutes, nor is it appropriate to treat multiproduct firms as if the introduction of a new good had no impact on the sales of existing goods.

Cannibalization rates rise with firm size, reflecting the fact that large firms take into account that more of their sales of new products comes at the expense of their existing products. However, we find an average cannibalization rate across all deciles of the firm size distribution that ranges between 0.50 and 0.51, which reflects the fact that even in the upper decile of the size distribution most firms have trivial market shares. In contrast, when the largest firm within a sector (which has an average market share of 22%) introduces a new product, we estimate that 61% of the sales of that product comes from the sales of its existing products. We saw from Table III that the largest firms typically have the most products per firm, so this implies that cannibalization is likely to be a first-order issue for them.³³

33. In Section S11 of the [Online Appendix](#), we compare our estimates of cannibalization effects to those in the marketing literature. In making this comparison, we note that the marketing literature uses different measures of cannibalization effects, and our model emphasizes that cannibalization effects vary across product groups (with elasticities of substitution) and across firms (with expenditure shares). Despite these caveats, our findings of substantial cannibalization effects

VI.E. Decomposing Firm Sales

The first panel of [Table X](#) presents the decompositions described in [equations \(18\)–\(22\)](#) for the full sample of firms and the second presents the results for the largest firms (those with a market share in excess of 0.5%). We run the results over both sets of firms to see if there are any differences between them. Overall, the results suggest a powerful role for firm appeal in accounting for the size of firms. The variance decomposition indicates that 76% of the overall size distribution can be attributed to firm appeal and 21% is attributed to scope. Thus, “total firm appeal” accounts for 97% of variation in firm sales. If we restrict ourselves to looking at the data for the fifty largest firms we still find that firm appeal explains on average 55% of the variation with scope accounting for 26%. In other words, even if we restrict our sample to the largest firms, variation in firm appeal accounts for around 80% of the variation across firms.

What is perhaps most surprising is the small role played by cost in the determination of firm size. There are two important features of this decomposition to bear in mind. First, a positive coefficient means that larger firms have lower costs: that is, cost differentials help explain size differentials. Second, our decomposition allows us to split firm-cost differentials into two components: average marginal cost differentials and the dispersion of costs across products (“cost dispersion”). In all cross-sectional decompositions, the cost dispersion term is positively correlated with firm size. The intuition is simple. Larger firms tend to sell more products and therefore are better positioned to benefit from cost differentials in supplying their consumption index. The results for average marginal costs are more mixed. In the full sample, we find almost no association between firm size and average costs, indicating that larger firms have essentially the same average marginal costs as smaller firms. Their total costs are lower because they can take advantage of the cost dispersion in their output. Interestingly, we find a stronger association with average costs when we restrict our sample to only the largest 50 firms. Here, we find that 17% of the firm-size distribution can be attributed to lower average costs of large firms and a quarter of

are broadly in line with the consensus in the existing empirical marketing literature.

TABLE X
VARIANCE DECOMPOSITIONS

Decomposition	Appeal	Scope	Average MC	Cost dispersion	Markup	Upgrading
Panel A: All firms						
Cross-sectional	0.758 (0.002)	0.2103 (0.0002)	-0.037 (0.002)	0.0706 (0.0001)	-0.00195 (0.00001)	
Firm growth	0.909 (0.009)	0.1581 (0.0013)	-0.135 (0.009)	0.0685 (0.0010)	-0.00060 (0.00004)	0.0004 (0.0014)
Panel B: Firms with >0.5% product-group share						
Cross-sectional	0.547 (0.013)	0.2638 (0.0016)	0.172 (0.013)	0.0614 (0.0008)	-0.04396 (0.00016)	
Firm growth	0.906 (0.053)	0.2627 (0.0080)	-0.169 (0.052)	0.0270 (0.0083)	-0.02620 (0.00129)	0.0226 (0.0140)

Notes. MC is marginal cost. Calculations on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

the overall distribution is explained by the two cost terms together. As discussed in Section VI.B, this ambiguous pattern of results reflects two offsetting effects. On the one hand, higher marginal costs directly reduce firm sales through a higher price. On the other hand, higher marginal costs are correlated with higher firm appeal, which raises firm sales. Finally markup variation, which depends on appeal and cost through expenditure shares, plays a relatively small role in explaining firm sales dispersion.³⁴

Figure I presents the results of the cross-sectional decomposition for the largest 50 firms in each product group. Each point represents the average contribution of a particular factor toward understanding the relative level of sales in a sector. For example, the column of points at the right of the figure indicate that the largest firm in a product group is on average almost nine log units larger than the average firm. Of this 9-log-unit difference the diamond-shaped point indicates that on average about 4.9 log units (54%) can be attributed to firm appeal differences. The circular point reveals that about 2.3 log units (25%) is on average attributable to scope differences, whereas the triangular and square points indicate that lower average costs and greater cost

34. Consistent with these findings, Roberts et al. (2011) find substantial heterogeneity in demand across Chinese footwear producers, while Foster, Haltiwanger, and Syverson (2015) emphasize the role of demand in the growth of entering firms.

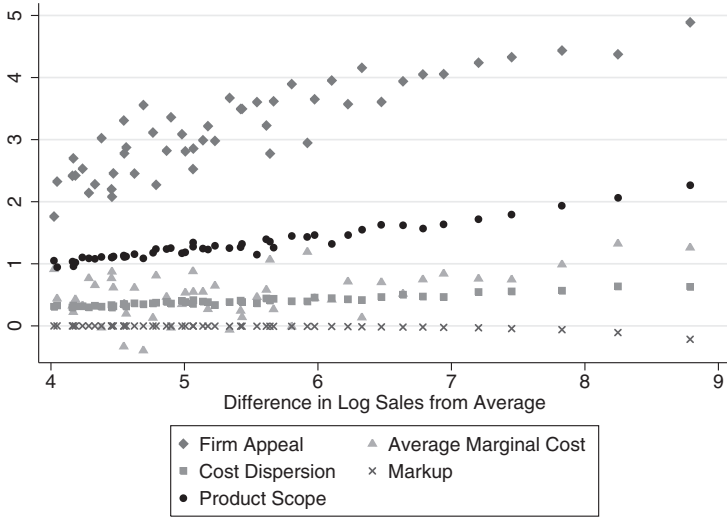

FIGURE I
Sales Decomposition by Firm Rank

The graph contains the weighted average across product groups (by quarter) of the decomposition of relative firm sales into the contributions of the firm appeal, marginal cost, markup, and product scope for the 50 firms with the largest average market share in 2004 and 2011. The vertical axis measures the contribution of each factor given by the left-hand sides of equations (18)–(22). The horizontal axis is the log difference between the firm’s sales and that of the average firm on the right-hand side of these equations. Calculated based on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

dispersion account for about 1.3 (14%) and 0.6 log units (7%) of sales. These percentages are extremely similar to the percentages for larger firms that we saw in Table X. However, the fact that each set of points is relatively tightly arrayed along a line indicates that the results presented in Table X are not the result of any outlier but are a robust feature of the data.³⁵

35. In principle, large firms could supply disproportionately more products than small firms for strategic reasons outside the model (e.g., to gain shelf space). If this were the case, one would expect the scatter of points corresponding to scope in Figure I to be convex. However, the relationship between size and scope is remarkably linear, which suggests that we do not observe this type of strategic behavior on average, although this does not rule out it mattering in some sectors.

There are two other features of the data that this plot also makes clear. First, we can see that although there is a tendency for average marginal costs to fall with size for the four largest firms, which accounts for the upward trend in the sequence of triangular points, this upward trend is not a robust feature of the data. This pattern helps explain why we found in [Table X](#) that average marginal costs did not fall with firm size when we looked at the full sample of firms, but did fall when we restricted our attention to the very largest firms. Moreover, we can see that the gains from increasing cost dispersion are a robust feature of the data.

The ability of the largest firms to exploit market power is also clearly seen in [Figure I](#). We saw in [Table X](#) that although markup variation played almost no role in understanding the firm-size distribution when we focused on the full sample of firms, it was negatively associated with firm sales when we examined the largest firms. [Figure I](#) shows that this negative association comes from the fact that if it were not for the fact that the very largest two or three firms had higher markups (a result we also saw in [Table IX](#)), their output levels would be higher. The implied inefficiently low levels of output of the largest firms suggest that the monopolistic competition model breaks down for these firms and motivates our attempt to quantify the implications of this pattern for aggregate consumer price indexes in [Section VIII](#).

As discussed in [Section IV.F](#), we can also examine the time-series determinants of firm growth by differencing with respect to time (i.e., using $\Delta^{g,t}$ instead of Δ^g in the decompositions). As shown in [Table X](#), appeal matters even more for firm growth. Virtually all of a firm's growth can be understood in terms of increases in appeal and scope, with cost changes playing almost no role. Interestingly, product upgrading—the addition of new, higher appeal products—plays little role in the typical firm's expansion. However, one must be cautious in the interpretation of this result for a number of reasons. First, this result does not include the important role played by scope as opposed to upgrading. Thus, if a firm innovates by adding new products of roughly the same appeal, we measure this as an expansion in scope, not appeal. Since we do find that changes in product scope play an important role in understanding firm growth, our findings should not be interpreted as suggesting that firms do not grow by adding new products. Indeed, over a quarter of the growth of large firms comes from this route.

Second, the result masks some important cross-sectoral heterogeneity. Some of our product groups, like frozen juice, flour, and eggs, exhibit low rates of barcode turnover reflecting the fact that these are mature sectors with little potential for innovation. In these sectors, there may be little scope for product upgrading. However, in the three highest turnover sectors (disposable diapers, photographic supplies, and electronics), we might expect to see product upgrading play a more important role. To investigate this, we created a measure of innovation in each product group. Following Broda and Weinstein (2010), we defined the product turnover rate as the total number of barcodes in 2004 that did not survive until 2010 plus the number of new barcodes in 2010 divided by the total number of barcodes that existed in 2004 and 2010. By construction, this index will equal 0 if there is no turnover of barcodes and 1 if all barcodes in 2010 are new. The index ranges from 0.3 for flour and 0.96 for photographic supplies, which corresponds to our priors about the importance of product innovation in these two sectors.

To see how important this heterogeneity is for understanding product upgrading, we regressed the importance of product upgrading for firm growth against how much product turnover occurs in a product group. We obtained a coefficient of 0.24 (std. err. 0.08). Similarly, we obtained a coefficient of 0.49 (std. err. 0.10) when we regressed the contribution of scope toward firm growth on product turnover. In other words, there is a clear statistical association between how important developing new and improved products are for understanding firm growth and the overall innovation rate in the sector. Firms in sectors with high rates of product turnover grow by developing new and improved products even more rapidly than their competitors, whereas this channel is almost absent in low-turnover sectors. These differences are economically significant. New and improved products (scope and turnover) account for 64% of firm growth in our three highest turnover sectors, but only 10% of firm growth in the three lowest turnover sectors. Although product upgrading alone accounts for 15% of firm growth in the three highest turnover sectors, it only accounts for 0.2% of firm growth in our three lowest turnover sectors.

Taken together, these decomposition results are quite striking in their consistency about the sources of firm heterogeneity. Regardless of whether we examine firms in the cross section or in the time series, improvements in firm appeal followed by product

scope are the most important drivers of firm sales for small and large firms alike. The role played by average marginal cost differences tends to be small and depend on the sample and decomposition method used. But we consistently find a positive contribution towards differences in firm size from the cost dispersion term. Finally, we see that although markup differences are unimportant determinants of firm sales for most firms, they do appear to be important for the very largest firms, something that suggests aggregate implications from the exploitation of market power by these firms.

VII. ROBUSTNESS

In this section, we demonstrate the robustness of our main finding that firm appeal accounts for most of the variation in firm sales to three sets of potential concerns: (i) theoretical specification, (ii) econometric estimation, and (iii) data and measurement.

VII.A. *Theoretical Specification*

The first class of concerns focuses on our nesting structure. One limitation of our approach is that to structurally estimate the model we need to assume a particular nesting structure for demand consisting of firms and products within firms. We choose this nesting structure to connect with the existing literature on measuring firm productivity (which implicitly or explicitly treats firms as a nest) and as a natural approach to modeling multiproduct firms. But it is reasonable to wonder whether our results are robust to other nesting structures.

In the [Online Appendix](#), we consider a number of generalizations of our approach, including other nested demand structures (Sections S2 and S3), the introduction of an additional nest for brands (Section S4), and a CES upper tier of utility (Section S5). Here we provide further evidence that our main empirical finding about the importance of appeal for sales variation is not sensitive to our assumed nesting structure. To do so, we use the CES functional form to derive a reduced-form equation that can be estimated for alternative nesting structures. Although this reduced-form equation cannot be used to recover structural parameters, it can be used to provide a lower bound on the importance of variation in appeal for alternative nesting structures.

We combine the following two results for CES demand. First, from equation (30), double-differenced expenditure shares depend on double-differenced price indexes for any tier of utility J . Second, from equation (32), the price index for this tier of utility J can be expressed in terms of expenditure shares and the geometric mean of prices for the lower tier of utility K . Together these two results yield the following reduced-form equation that can be estimated using OLS:

$$(35) \quad \Delta^{j,t} \ln S_{jgt}^J = \alpha_g + \beta_{1g} \Delta^{j,t} \ln \tilde{P}_{jgt}^K + \beta_{2g} \Delta^{j,t} \ln \left[\sum_{k \in \Omega_{jgt}^K} \frac{S_{kt}^K}{\tilde{S}_{jgt}^K} \right] + \varepsilon_{jgt},$$

where $j \in \Omega_{gt}^J$ indexes varieties in utility tier J and $k \in \Omega_{jgt}^K$ indexes varieties in the lower utility tier K ; $\Delta^{j,t}$ is the double-difference operator across varieties j and over time t ; we allow the parameters $\{\alpha_g, \beta_{1g}, \beta_{2g}\}$ to vary across product groups g ; $\tilde{P}_{jgt}^K = \exp \left\{ \frac{1}{N_{jgt}^K} \sum_{k=1}^{N_{jgt}^K} \ln P_{kt}^K \right\}$ and the error ε_{jgt} captures double-differenced appeal ($\Delta^{j,t} \ln \varphi_{jgt}^J$).

In our structural model, β_{2g} can be related to structural parameters of the model ($\beta_{2g} = \frac{1}{\sigma_g^k - 1}$). In the reduced-form regression (equation (35)), this coefficient does not have a structural interpretation, because the term in appeal for tier j (ε_{jgt}) can be correlated with the geometric mean of prices in the lower tier k (\tilde{P}_{jgt}^K). Therefore, if equation (35) is estimated using OLS, the coefficient β_{2g} is subject to omitted variable bias and is not consistently estimated. For this reason, we use our structural approach developed above to estimate the model's parameters for our assumed nesting structure.

Nonetheless, equation (35) can be used to provide a lower bound on the importance of appeal for alternative nesting structures. The reason that this specification provides a lower bound is that changes in appeal are captured in the estimated residual ($\hat{\varepsilon}_{jgt}$). Therefore, the component of appeal that is correlated with the explanatory variables is attributed to the coefficients $\{\beta_{1g}, \beta_{2g}\}$ on these explanatory variables, leaving only the orthogonal component of appeal in the estimated residual ($\hat{\varepsilon}_{jgt}$).

TABLE XI
WITHIN NEST R^2

Specification	Nest 1	Nest 2	Nest 3	Nest 4	Mean	Std. dev.
I	Product group	Firm	UPC	N/A	0.53	0.05
II	Product group	Brand-module	UPC	N/A	0.46	0.06
III	Product group	Firm-module	UPC	N/A	0.47	0.07
IV	Module	Brand-module	UPC	N/A	0.48	0.06
V	Module	Firm-module	UPC	N/A	0.49	0.05
VI	Module	Firm-module	Brand	UPC	0.57	0.07

Notes. Calculations on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

In Table XI, we report the average R^2 across all product groups from estimating this reduced-form regression for alternative nesting structures, where 1 minus this R^2 corresponds to the variance in double-differenced expenditure shares that is unexplained by the explanatory variables (and is instead explained by appeal). We estimate the regression separately for each product group and quarter and summarize the mean and standard deviation of the R^2 , weighting each product group and quarter by their sales.

In the first row of the table, we report results for our assumed nesting structure. In the remaining rows, we report results for a wide range of alternative nesting structures. While there are 98 product groups, Nielsen subdivides these into approximately 1,000 “modules,” which are finer categories (e.g., “Nutritional Supplements” is a product group, and “Multi-Vitamins” is a module). “Firm-modules” correspond to all barcodes in a module sold by a firm (e.g., “Wyeth”), and “Brand-modules” are even more narrow nests consisting of all barcodes sold by a firm in a module under a particular brand (e.g., “Centrum” and “Centrum Performance”). Some of these alternative nesting structures disaggregate firms relative to our baseline specification (e.g., Specification II uses Product Group and Brand-Module instead of Product Group and Firm). Other alternative nesting structures omit firms as a nest altogether (e.g., Specification IV uses Module and Brand-Module). Across this wide range of specifications, we find that appeal accounts for at least 43% of the variation in double-differenced sales. Thus, regardless of one’s choice of nesting structure, it is hard to escape the conclusion

that around half of sales variation is attributable to variation in appeal. Since this lower bound also leaves out the important role played by scope, this further reinforces the importance of total appeal (including scope) in explaining sales variation.

VII.B. *Econometric Estimation*

Our firm sales decomposition depends on the model's parameters, and hence a second class of concerns relates to the estimation of these parameters. At the simplest level, one might worry about whether our estimation procedure in Sections V.B and V.C can successfully recover the model's parameters. To address this concern, we undertake a Monte Carlo simulation (Section S8 of the [Online Appendix](#)), in which we show that our estimation procedure consistently recovers the true parameters when the data are generated from the model. Therefore our estimation procedure works when our identifying assumptions are satisfied.

However, what if our identifying assumptions are not satisfied? As a first step to addressing this concern, we report a number of additional specification checks. First, we use the fact that we have data on different brands supplied by firms within product groups. Therefore, instead of double differencing relative to a firm's largest product, we double difference relative to a firm's largest product within the same brand. We continue to find a similar pattern of results as in our baseline specification, which suggests that our estimates are not driven by shocks to both demand and supply for brands.³⁶ Second, under our identifying assumption that double-differenced demand and supply shocks are orthogonal to one another, the time interval over which we difference should not affect the results. In contrast, if demand and supply shocks are correlated, the time interval over which we difference could matter, because for example of seasonal fluctuations in demand. Estimating over time intervals ranging from a quarter to a year, we continue to find a similar pattern of results, consistent with our identifying assumption.³⁷

36. Differencing within brands (rather than within firms), we find median estimates for σ^U of 6.49 (compared to 6.93 in our baseline specification) and for σ^F of 3.74 (compared to 3.92 in our baseline specification).

37. Differencing over years rather than over quarters, we find median estimates for σ^U of 7.06 (compared to 6.93 in our baseline specification) and for σ^F of 4.37 (compared to 3.92 in our baseline specification).

Nonetheless, there could be further econometric concerns or data issues that are not fully addressed in these robustness checks. Fortunately, it is easy to deal with concerns about whether our particular elasticity estimates are driving our firm sales decomposition results. Put simply, if our decomposition results are influenced by an estimation problem, then we should obtain different results from this decomposition using different values for the model's parameters. We therefore can dispose of this concern by examining the sensitivity of our decomposition of firm sales (equation (15)) to all reasonable estimates of the model's parameters.

In Section S7 of the [Online Appendix](#), we report the results of a grid search over a wide range of values for the elasticities of substitution $\{\sigma_g^U, \sigma_g^F\}$. In particular, we consider a range of possible values for σ_g^F at intervals of 0.5 from 2 (half our median estimate for σ_g^F) to 12 (four times our median estimate for σ_g^F) and σ_g^U ranging from 2.5 (just under half the median estimate) to 20 (almost triple the median estimate). Consistent with our empirical estimates above, we restrict attention to values on this parameter grid for which $\sigma_g^U > \sigma_g^F > 1$. For each parameter configuration, we replicate our firm sales decomposition (equation (15)), which holds regardless of the value for δ_g because it is based on observed prices. Naturally, the precise relative contribution of each component varies depending on parameter values. But we find that firm appeal and scope account for more than 80% of firm sales variation (and firm appeal alone accounts for at least 50% of firm sales variation) across the wide range of parameter values on the grid. In other words, the result that firm appeal and scope are the main determinants of firm size is a deep feature of looking at the world through a CES setup and is not dependent on our particular elasticity estimates. The underlying feature of the data driving this result is the substantial variation in firm sales conditional on price. For plausible values of the elasticity of substitution, the model cannot explain this sales variation by price variation, and hence it is attributed to appeal. While we derive our results for a CES setup, we conjecture that this underlying feature of the data would generate a substantial role for demand shifters in explaining firm sales variation for a range of plausible demand systems.

VII.C. *Data and Measurement*

A third class of concerns relates to data and measurement. We use data on barcodes because they correspond closely to the economic concept of a product and hold observable product characteristics constant. But one might worry that marketing, taste, and other nontechnical dimensions of appeal might be more important for consumer nondurables than for traded goods (which include intermediate inputs) or consumer durables. Alternatively, one might worry that because we do not have data on wholesale prices, we are missing important variation in retail markups or marketing. To address these concerns, Section S9 of the [Online Appendix](#) reestimates our econometric specification using Chilean international trade transactions data. Despite the use of different types of data and different definitions of products (e.g., barcodes versus eight-digit HS products), we continue to find that most of firm sales variation is explained by firm appeal and scope. Therefore, our findings are not dependent on our data and apply to other types of goods.

VIII. FIRM AND AGGREGATE IMPLICATIONS

Thus far, we have been focused on using our structural model to quantify the sources of firm heterogeneity. However, our results also have implications for the measurement of firm productivity and the aggregate consequences of departures from the benchmark of monopolistic competition. We now consider these implications.

VIII.A. *Firm Output and Productivity*

All productivity estimates are based on a concept of real output, which in theory equals nominal output divided by a price index, but the choice of price index is not arbitrary: it is determined by the utility function. In other words, for multiproduct firms, the concept of real output is not independent of the demand system, so all attempts to measure productivity based on a real output concept contain an implicit assumption about the structure of the demand system.³⁸

38. Since firms supply differentiated products, the relevant measure of productivity is TFPR (Foster, Haltiwanger, and Syverson 2008), which necessarily depends on prices and hence the specification of demand.

We can see how much it matters whether a researcher takes into account the fact that virtually all firms produce more than one product by considering two approaches to measuring firm output. The first is a “commonsense” or conventional price index, $\mathbb{P}_{f_{gt}}^F$, which is a quantity-weighted average price of a firm’s output. The second is the CES price index, which equals nominal output divided by the minimum expenditure necessary to generate a unit of utility (see [Sato 1976](#) and [Vartia 1976](#)). According to [equation \(1\)](#), the quality-adjusted flow of consumption from a firm’s output is $\varphi_{f_{gt}}^F C_{f_{gt}}^F$, so the corresponding expenditure function for a unit of consumption is $\frac{P_{f_{gt}}^F}{\varphi_{f_{gt}}^F}$.

Obviously, different price index formulas will yield different measures of prices, but there are two issues: how big is the measurement error and is the commonsense approach biased? It’s easy to see that the answer to the second question must be “yes.” [Equation \(32\)](#) indicates that in the CES system, the use of average goods prices to measure firm-level prices will overstate the price level (and understate real output) more for large, multi-product firms than for small, single-product ones. Therefore, if the true model is CES but a researcher uses a conventional price index, the results are likely to underestimate the output of large firms relative to small firms.

We can understand the magnitudes of the measurement error and bias of conventional approaches through a simple exercise. If we denote the consumer’s expenditure on a firm’s output by $E_{f_{gt}}^F$, we can write the conventional measure of real output, $\mathbb{Q}_{f_{gt}}^F$, as $\frac{E_{f_{gt}}^F}{\mathbb{P}_{f_{gt}}^F}$, and the CES measure of real output, $Q_{f_{gt}}^F$, as $\frac{E_{f_{gt}}^F}{\frac{P_{f_{gt}}^F}{\varphi_{f_{gt}}^F}}$.

These measures will vary across sectors due to the units, so to compare size variation across sectors we will work with unitless shares of each firm in sectoral output (i.e., $\sum_{f \in \Omega_{gt}^F} \frac{Q_{f_{gt}}^F}{Q_{f_{gt}}^F}$ and $\sum_{f \in \Omega_{gt}^F} \frac{\mathbb{Q}_{f_{gt}}^F}{\mathbb{Q}_{f_{gt}}^F}$).

[Figure II](#) plots these two measures of real output. We place the CES market shares on the horizontal axis because the conventional index is only correct in the special case in which the elasticity of substitution is infinite and therefore output measures computed using the conventional index are likely to be measured with error. As one can see in [Figure II](#), the choice of price

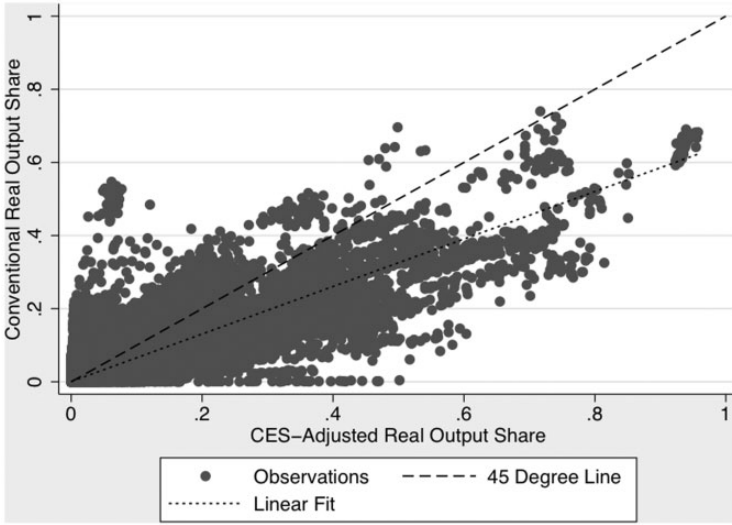

FIGURE II
Bias in Conventional Real Output Share

Calculated based on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

index matters enormously for the computation of real output. If one regresses $\sum_{f \in \Omega_{gt}^F} \frac{Q_{fgt}^F}{Q_{fgt}^F}$ on $\sum_{f \in \Omega_{gt}^F} \frac{Q_{fgt}^F}{Q_{fgt}^F}$, one only obtains an R^2 of 0.77

with a coefficient of 0.65 (std. err. 0.004). These results imply that about a quarter of the variation of firm-level real output one would obtain by using a conventional price index is simply due to the fact the conventional price index assumes that firms produce homogeneous output—an assumption that easily can be rejected. Moreover, studies based on conventional measures of firm prices understate the real output of large firms by a third relative to small firms, with implications for estimates of returns to scale and productivity. Even if one does not believe that the CES framework is the right one to measure demand, the results mean that the implicit choice of demand system contained in a price index is of first-order importance in the measurement of real output.

VIII.B. Aggregate Consumer Price Indexes

We now turn to the implications of our estimates for aggregate consumer price indexes. We undertake two counterfactuals to highlight the quantitative relevance of our departures from the benchmark of single-product, monopolistically competitive firms. First we consider the implications of a regulator preventing large firms from exercising their market power and thereby requiring each firm to compete under monopolistic competition. Second we consider the implications of allowing firms to supply a number of differentiated products. Thus, this second counterfactual examines the effect on the consumer price index from the different varieties supplied by each firm.

In each counterfactual, we report results for Bertrand and Cournot competition. In each case, we hold constant aggregate expenditure, factor prices, the sets of active UPCs and firms $\{\Omega_{igt}^U, \Omega_{igt}^F\}$, firm and product appeal $\{\varphi_{igt}^F, \varphi_{ut}^U\}$, and the cost shifters $\{a_{ut}\}$. Therefore we abstract from the effect of changes in profits on aggregate expenditure. We also abstract from general equilibrium effects through firm entry and exit. Our goal is not to capture the full general equilibrium effects of each counterfactual, but to show that our firm-level estimates are of quantitative relevance for aggregate consumer price indexes.

In the first set of counterfactuals (I-B and I-C), we compare the actual equilibrium in which firms exploit their market power with a counterfactual equilibrium in which a price regulator requires all firms to charge the same constant markup over marginal cost equal to the monopolistically competitive firm markup:

$$(36) \quad \mu_{igt}^F = \frac{\sigma_g^F}{\sigma_g^F - 1}.$$

Moving from the actual to the counterfactual markup reduces the relative prices of successful firms with high market shares and hence redistributes market shares toward these firms. Therefore, we expect these counterfactuals to reduce the consumer price index and increase the dispersion of firm sales, but the magnitude of these effects depends on the estimated parameters $\{\sigma_g^U, \sigma_g^F, \delta_g\}$, firm and product appeal $\{\varphi_{igt}^F, \varphi_{ut}^U\}$, and the cost shifters $\{a_{ut}\}$.

Given the assumed constant markup in equation (36), we solve for the counterfactual equilibrium using an iterative

procedure to solve for a fixed point in a system of five equations for expenditure shares and price indexes $\{S_{ut}^U, P_{ut}^U, S_{igt}^F, P_{igt}^F, P_{gt}^G\}$. These five equations are the UPC expenditure share (given by equation (4) for UPCs), the UPC pricing rule (equation (9)), the firm expenditure share (given by equation (4) for firms), the firm price index (given by equation (3) for firms) and the product group price index (given by equation (3) for product groups). We use the resulting solutions for product group price indexes to compute the aggregate consumer price index: $\prod_{g=1}^G (P_{gt}^G)^{\phi_{gt}}$.

In Counterfactuals II-B and II-C, we examine the quantitative relevance of multiproduct firms. We compare the actual equilibrium in which firms supply multiple products to a counterfactual equilibrium in which firms are restricted to supply a single UPC (their largest). Counterfactual II-B undertakes this comparison assuming Bertrand competition, whereas Counterfactual II-C undertakes the same comparison assuming Cournot competition. We again solve for the counterfactual equilibrium by solving for a fixed point in the system of five equations for expenditure shares and price indexes.

Table XII reports the results from both sets of counterfactuals. Each row of the table corresponds to a different counterfactual. Each column reports the value of a variable in the counterfactual relative to that in the actual data. The second column reports the relative coefficient of variation of firm sales. The third column reports the relative consumer price index.

In Counterfactual I-B, we find that moving from Bertrand to monopolistic competition reduces the consumer price index by around 4%, which is quantitatively relevant compared to standard estimates of the welfare gains from trade for an economy such as the United States. In Counterfactual I-C, we find much larger effects from moving from Cournot to monopolistic competition, which reduces the consumer price index by around 13%. These much larger effects reflect the fact that large firms charge much higher markups under Cournot than under Bertrand competition as we saw in Table IX. This result implies larger price reductions from moving to monopolistically competitive markups, and hence larger reductions in the consumer price index. In Counterfactuals I-B and I-C, the relative prices of the largest firms fall and demand is elastic. Therefore, the coefficient of variation of firms sales increases, by around 11% for Bertrand competition and around 39% for Cournot competition. Again, the

TABLE XII
COUNTERFACTUAL EXERCISES (RELATIVE TO OBSERVED)

	Coef. var. firm sales	Consumer price index
I-B: Bertrand to monopolistic competition	1.11	0.96
I-C: Cournot to monopolistic competition	1.39	0.87
II-B: Multiproduct to single-product Bertrand	0.83	1.49
II-C: Multiproduct to single-product Cournot	0.86	1.47

Notes. Each statistic is expressed as the value in the counterfactual divided by the value in the observed data. Calculations on data from the Nielsen Company (U.S.) and provided by the Marketing Data Center at the University of Chicago Booth School of Business.

larger effects for Cournot reflect the greater variation in markups under this mode of competition.

In Counterfactuals II-B and II-C, we find quantitatively large effects of multiproduct firms. Restricting firms to supply a single product under Bertrand competition increases the consumer price index by around 49% and reduces the coefficient of variation of firm sales by around 17%. The corresponding increase in the consumer price index and reduction in the coefficient of variation of firm sales under Cournot competition are similar: 47% and 14%, respectively. These results suggest that consumers benefit enormously from the range of products supplied within a single firm.

All of these counterfactuals are subject to a number of caveats. In particular, they do not allow for firm entry or exit, because they hold the set of firms constant, and they abstract from the effect of changes in profits on aggregate expenditure. Nonetheless, these counterfactuals establish the quantitative relevance of our departures from the case of monopolistic competition with single product firms.

IX. CONCLUSIONS

We develop and structurally estimate a model of heterogeneous multiproduct firms that can be used to decompose the firm-size distribution into the contributions of costs, appeal, scope, and markups. Our framework requires only price and expenditure data and hence is widely applicable. We use these price and expenditure data to estimate the key parameters of the model, namely, the elasticities of substitution between and within

firms, and the elasticities of marginal cost with respect to output. We use the resulting parameter estimates and the structure of the model to recover overall firm and product appeal, marginal costs, the number of products a firm supplies, and the firm's markup.

Our results point to differences in firm appeal as being the principal reason some firms are large and others are not. Depending on the specification considered, we find that 50–75% of the variance in firm size can be attributed to differences in appeal, about 20–25% to differences in product scope, and less than 20% to average marginal cost differences. If we use a broad measure of total firm appeal, which encompasses both firm appeal as well as scope, we find that total firm appeal accounts for almost all of firm size differences.

We estimate substantially higher elasticities of substitution between varieties within firms than between firms (median elasticities of 6.9 and 3.9, respectively), implying that a firm's introduction of new product varieties cannibalizes the sales of existing varieties. We estimate that the cannibalization rate for the typical firm is 0.50, roughly halfway between the extreme of no cannibalization (equal elasticities of substitution within and between monopolistically competitive firms), and the extreme of complete cannibalization (varieties perfectly substitutable within firms).

We find that the typical sector comprises a few large firms with substantial market shares and a competitive fringe of firms with trivial market shares. Therefore most firms charge markups close to the monopolistic competition benchmark of constant markups, because they have trivial market shares and hence are unable to exploit their market power. However, the largest firm accounts on average for 22% of sales in a sector, and the median largest firm charges a markup between 24% and 100% higher than the average firm within the same sector. Using the estimated model to undertake counterfactuals, we find that these departures from the monopolistically competitive benchmark raise aggregate consumer price indexes by between 4% and 13%.

Our findings that firms supply multiple imperfectly substitutable varieties have important implications for the measurement of firm productivity, highlighting the role of assumptions about demand in the measurement of productivity for multiproduct firms. Conventional price indexes based on a weighted average of firm prices do not take into account that the theoretical price index for the firm depends on the number of products it

supplies whenever consumers care about variety. Indeed, our counterfactual exercise indicates that the multiple varieties supplied by multiproduct firms reduce the aggregate consumer price index by around one third. Moreover, ignoring this effect introduces a systematic bias into the measurement of firm productivity, because larger firms supply more products than smaller firms. We find this bias to be quantitatively large. An increase in firm sales is associated with around a one third larger increase in true real output (using the exact price index) than in measured real output (using the conventional price index).

APPENDIX A: DERIVATIONS
DERIVATION OF EQUATIONS (7)–(9)

The first-order condition with respect to the price of an individual UPC implies:

$$(37) \quad Y_{ut}^U + \sum_{k=\underline{u}_{fgt}}^{\underline{u}_{fgt}+N_{fgt}^U} \left(P_{kt}^U \frac{dY_{kt}^U}{dP_{ut}^U} - \frac{dA_{kt}(Y_{kt}^U)}{dY_{kt}^U} \frac{dY_{kt}^U}{dP_{ut}^U} \right) = 0.$$

Using equation (5) and setting UPC supply equal to demand we have

$$\frac{\partial Y_{kt}^U}{\partial P_{ut}^U} = (\sigma^F - 1) \frac{Y_{kt}^U}{P_{gt}^G} \frac{\partial P_{gt}^G}{\partial P_{ut}^U} + (\sigma^U - \sigma^F) \frac{Y_{kt}^U}{P_{fgt}^F} \frac{\partial P_{fgt}^F}{\partial P_{ut}^U} - \sigma_u \frac{Y_{kt}^U}{P_{ut}^U} \frac{\partial P_{kt}^U}{\partial P_{ut}^U}.$$

We now can use equation (4) to solve for the elasticities and rewrite $\frac{\partial Y_{kt}^U}{\partial P_{ut}^U}$ as

$$(38) \quad \begin{aligned} \frac{\partial Y_{kt}^U}{\partial P_{ut}^U} &= (\sigma^F - 1) \left(\frac{\partial P_{gt}^G}{\partial P_{fgt}^F} \frac{P_{fgt}^F}{P_{gt}^G} \right) \left(\frac{\partial P_{fgt}^F}{\partial P_{ut}^U} \frac{P_{ut}^U}{P_{fgt}^F} \right) \frac{Y_{kt}^U}{P_{ut}^U} \\ &+ (\sigma^U - \sigma^F) \left(\frac{\partial P_{fgt}^F}{\partial P_{ut}^U} \frac{P_{ut}^U}{P_{fgt}^F} \right) \frac{Y_{kt}^U}{P_{ut}^U} - \sigma^U \frac{Y_{kt}^U}{P_{ut}^U} \mathbf{1}_{\{u=k\}} \\ &= (\sigma^F - 1) S_{fgt}^F S_{ut}^U \frac{Y_{kt}^U}{P_{ut}^U} + (\sigma^U - \sigma^F) S_{ut}^U \frac{Y_{kt}^U}{P_{ut}^U} - \sigma^U \frac{Y_{kt}^U}{P_{ut}^U} \mathbf{1}_{\{u=k\}}. \end{aligned}$$

If we now substitute equation (38) into equation (37) and divide both sides by Y_u^U , we get

$$\begin{aligned}
 & 1 + \sum_k (\sigma^F - 1) S_{fgt}^F S_{ut}^U \frac{P_{kt}^U Y_{kt}^U}{P_{ut}^U Y_{ut}^U} + \sum_k (\sigma^U - \sigma^F) S_{ut}^U \frac{P_{kt}^U Y_{kt}^U}{P_{ut}^U Y_{ut}^U} - \sigma^U \\
 & - \sum_k (\sigma^F - 1) S_{fgt}^F S_{ut}^U \frac{\frac{\partial A_{kt}(Y_{kt}^U)}{\partial Y_{kt}^U} Y_{kt}^U}{P_{ut}^U Y_{ut}^U} - \sum_k (\sigma^U - \sigma^F) S_{ut}^U \frac{\frac{\partial A_{kt}(Y_{kt}^U)}{\partial Y_{kt}^U} Y_{kt}^U}{P_{ut}^U Y_{ut}^U} \\
 & + \sigma_u \frac{\frac{\partial A_{kt}(Y_{kt}^U)}{\partial Y_{kt}^U}}{P_{ut}^U} = 0.
 \end{aligned}
 \tag{39}$$

We define the markup as $\mu_{kt} \equiv \frac{P_{kt}^U}{\frac{\partial A_{kt}(Y_{kt}^U)}{\partial Y_{kt}^U}}$. Since $S_{ut}^U \frac{1}{P_{ut}^U Y_{ut}^U} = \frac{1}{\sum_k P_{kt}^U Y_{kt}^U}$ and therefore $\sum_k S_{ut}^U \frac{P_{kt}^U Y_{kt}^U}{P_{ut}^U Y_{ut}^U} = 1$, we can rewrite equation (39) as

$$\begin{aligned}
 & 1 + (\sigma^F - 1) S_{fgt}^F + (\sigma^U - \sigma^F) - \sigma^U - (\sigma^F - 1) S_{fgt}^F \frac{\sum_k \frac{\partial A_{kt}(Y_{kt}^U)}{\partial Y_{kt}^U} Y_{kt}^U}{\sum_k P_{kt}^U Y_{kt}^U} \\
 & - (\sigma^U - \sigma^F) \frac{\sum_k \frac{\partial A_{kt}(Y_{kt}^U)}{\partial Y_{kt}^U} Y_{kt}^U}{\sum_k P_{kt}^U Y_{kt}^U} + \sigma^U \frac{1}{\mu_{ut}} = 0.
 \end{aligned}$$

Because we assume that σ^U is the same for all u produced by a firm, μ_{ut} is the only u -specific term in this expression. Hence, μ_{ut} must be constant for all u produced by firm f in time t ; in other words, markups only vary at the firm level. Together these two results ensure the same markup across all UPCs supplied by the firm.

We can now solve for μ_{ft}^F by

$$1 + (\sigma^F - 1)S_{fgt}^F + (\sigma^U - \sigma^F) - \sigma^U - (\sigma^F - 1)S_{fgt}^F \frac{1}{\mu_{ft}^F} - (\sigma^U - \sigma^F) \frac{1}{\mu_{ft}^F} + \sigma^U \frac{1}{\mu_{ft}^F} = 0$$

$$\Rightarrow \mu_{ft}^F = \frac{\sigma^F - (\sigma^F - 1)S_{fgt}^F}{\sigma^F - (\sigma^F - 1)S_{fgt}^F - 1}.$$

DERIVATION OF EQUATION (13)

Equilibrium price indexes P_{gt}^G and P_{fgt}^F are functions of the number of products N_{fgt}^U . Recall that demand for UPC u supplied by firm f within product group g is:

$$Y_{ut}^U = (\varphi_{fgt}^F)^{\sigma^F - 1} (\varphi_{ut}^U)^{\sigma^U - 1} E_{gt}^G (P_{gt}^G)^{\sigma^F - 1} (P_{fgt}^F)^{\sigma^U - \sigma^F} (P_{ut}^U)^{-\sigma^U}.$$

Now suppose that the number of UPCs supplied by the firm (N_{fgt}^U) can be approximated by a continuous variable and consider the partial elasticity of Y_{ut}^U with respect to this measure of UPCs:

$$\begin{aligned} \frac{\partial Y_{ut}^U}{\partial N_{fgt}^U} &= (\sigma^F - 1) \frac{Y_{ut}^U}{P_{gt}^G} \frac{\partial P_{gt}^G}{\partial N_{fgt}^U} + (\sigma^U - \sigma^F) \frac{Y_{kt}^U}{P_{fgt}^F} \frac{\partial P_{fgt}^F}{\partial N_{fgt}^U}, \\ &= (\sigma^F - 1) \frac{Y_{ut}^U}{P_{gt}^G} \frac{N_{fgt}^U}{P_{fgt}^F} \frac{P_{fgt}^F}{N_{fgt}^U} \frac{\partial P_{gt}^G}{\partial N_{fgt}^U} \frac{\partial P_{fgt}^F}{\partial N_{fgt}^U} + (\sigma^U - \sigma^F) \frac{Y_{kt}^U}{P_{fgt}^F} \frac{N_{fgt}^U}{N_{fgt}^U} \frac{\partial P_{fgt}^F}{\partial N_{fgt}^U}, \\ &= (\sigma^F - 1) \left(\frac{\partial P_{gt}^G}{\partial P_{fgt}^F} \frac{P_{fgt}^F}{P_{gt}^G} \right) \left(\frac{\partial P_{fgt}^F}{\partial N_{fgt}^U} \frac{N_{fgt}^U}{P_{fgt}^F} \right) \frac{Y_{ut}^U}{N_{fgt}^U} + (\sigma^U - \sigma^F) \left(\frac{\partial P_{fgt}^F}{\partial N_{fgt}^U} \frac{N_{fgt}^U}{P_{fgt}^F} \right) \frac{Y_{kt}^U}{N_{fgt}^U}, \end{aligned}$$

where this partial elasticity holds constant the prices of existing UPCs. Using equation (3) for the firm price index and equation (4) for the UPC expenditure share, we have:

$$\frac{\partial P_{fgt}^F}{\partial N_{fgt}^U} \frac{N_{fgt}^U}{P_{fgt}^F} = \frac{\left(\frac{P_{N_{fgt}^U}^U}{\varphi_{N_{fgt}^U}^U} \right)^{1 - \sigma^U}}{1 - \sigma^U} \left(P_{fgt}^F \right)^{\sigma^U} \frac{N_{fgt}^U}{P_{fgt}^F} = \frac{N_{fgt}^U}{1 - \sigma^U} \frac{\left(\frac{P_{N_{fgt}^U}^U}{\varphi_{N_{fgt}^U}^U} \right)^{1 - \sigma^U}}{\sum_{k=1}^{N_{fgt}^U} \left(\frac{P_{kt}^U}{\varphi_{kt}^U} \right)^{1 - \sigma^U}} = \frac{N_{fgt}^U}{1 - \sigma^U} S_{N_{fgt}^U}^U.$$

Recalling that expenditure shares are also the elasticities of the price index with respect to prices, we obtain:

$$\begin{aligned} \text{Cannibalization} &\equiv -\frac{\partial Y_{ut}^U N_{fgt}^U}{\partial N_{fgt}^U Y_{ut}^U} = -(\sigma^F - 1)S_{fgt}^F \frac{N_{fgt}^U}{1 - \sigma^U} S_{N_{fgt}^U}^U - (\sigma^U - \sigma^F) \frac{N_{fgt}^U}{1 - \sigma^U} S_{N_{fgt}^U}^U \\ &= \left[\left(\frac{\sigma^U - \sigma^F}{\sigma^U - 1} \right) + \left(\frac{\sigma^F - 1}{\sigma^U - 1} \right) S_{fgt}^F \right] S_{N_{fgt}^U}^U N_{fgt}^U > 0, \quad \text{for } \sigma^U \geq \sigma^F > 1. \end{aligned}$$

Note that this derivation is based solely on the derivatives of the CES price index with respect to the measure of UPCs and observed prices. Since the assumption of Bertrand or Cournot competition merely affects the decomposition of observed prices into markups and marginal costs, these derivatives are the same under both forms of competition. Therefore the derivation of the cannibalization rate is the same under both forms of competition.

COURNOT QUANTITY COMPETITION

In our baseline specification in the main text, we assume that firms choose prices under Bertrand competition. Here we discuss a robustness test in which we assume instead that firms choose quantities under Cournot competition. Each firm chooses the number of UPCs (N_{fgt}^U) and their quantities (Y_{ut}^U) to maximize its profits:

$$\max_{\{\underline{u}_{fgt}, \dots, \bar{u}_{fgt}\}, \{Y_{ut}^U\}} \Pi_{fgt}^F = \sum_{u=\underline{u}_{fgt}}^{\underline{u}_{fgt} + N_{fgt}^U} P_{ut}^U Y_{ut}^U - A_{ut}(Y_{ut}^U) - N_{fgt}^U H_{gt}^U - H_{gt}^F, \tag{40}$$

where we again index the UPCs supplied by the firm from the largest to the smallest in sales. From the first-order conditions for profit maximization, we obtain the equilibrium markup:

$$\mu_{fgt}^F = \frac{\varepsilon_{fgt}^F}{\varepsilon_{fgt}^F - 1}, \tag{41}$$

where the firm's perceived elasticity of demand is now:

$$\varepsilon_{fgt}^F = \frac{1}{\frac{1}{\sigma^F} - \left(\frac{1}{\sigma^F} - 1\right) S_{fgt}^F}, \tag{42}$$

and the firm's pricing rule is:

$$(43) \quad P_{ut}^U = \mu_{fgt}^F \frac{dA_{ut}(Y_{ut}^U)}{dY_{ut}^U} = \mu_{fgt}^F [(1 + \delta)a_{ut}(Y_{ut}^U)^\delta].$$

Therefore the analysis with Cournot competition in quantities is similar to that with Bertrand competition in prices, except that firms' perceived elasticities of demand (ε_{fgt}^F) and hence their markups differ between these two cases. Since firms internalize their effects on product group aggregates, markups are again variable. Furthermore, markups are common across UPCs within a given firm and product group, but vary across product groups within firms for the reasons discussed in the main text.

Our estimation procedure for $\{\sigma^U, \sigma^F, \delta\}$ remains entirely unchanged because the firm markup differences out when we take double differences between a pair of UPCs within the firm over time. Therefore our estimates of the parameters $\{\sigma^U, \sigma^F, \delta\}$ are robust to the assumption of either Bertrand or Cournot competition. Our solutions for firm and product quality $\{\varphi^U, \varphi^F, \delta\}$ are also unchanged because they depend solely on observed expenditure shares and prices $\{S_{ut}^U, S_{fgt}^F, P_{ut}^U\}$ and our estimates of the parameters $\{\varphi^U, \varphi^F, \delta\}$. Therefore whether we assume Cournot or Bertrand competition is only consequential for the decomposition of observed UPC prices (P_{ut}^U) into markups (μ_{fgt}^F) and marginal costs (a_{ut}). Markups are somewhat more variable in the case of Cournot competition, which strengthens our finding of substantial departures from the monopolistically competitive markup for the largest firms within each product group.

RELATIVE FIRM MARKUPS UNDER BERTRAND COMPETITION

For firms with nonnegligible shares of expenditure within a product group ($0 < S_{fgt}^F < 1$):

$$\mu_{fgt}^F - 1 = \left(\frac{\sigma^F - (\sigma^F - 1)S_{fgt}^F}{\sigma^F - (\sigma^F - 1)S_{fgt}^F - 1} \right) - 1.$$

For a firm with a negligible share of expenditure within a product group ($S_{f_{gt}}^F \approx 0$):

$$\mu_{f_{gt}}^F - 1 = \left(\frac{\sigma^F}{\sigma^F - 1} \right) - 1.$$

The ratio of the two markups (for σ^F finite and $S_{f_{gt}}^F < 1$) is:

$$\frac{1}{1 - S_{f_{gt}}^F}.$$

Therefore the dispersion of relative markups under Bertrand competition depends solely on the dispersion of expenditure shares.

RELATIVE FIRM MARKUPS UNDER COURNOT COMPETITION

For firms with nonnegligible shares of expenditure within a product group ($0 < S_{f_{gt}}^F < 1$):

$$\mu_{f_{gt}}^F - 1 = \left(\frac{\frac{1}{\sigma^F - (\frac{1}{\sigma^F} - 1)S_{f_{gt}}^F}}{\frac{1}{\sigma^F - (\frac{1}{\sigma^F} - 1)S_{f_{gt}}^F} - 1} \right) - 1.$$

For a firm with a negligible share of expenditure within a product group ($S_{f_{gt}}^F \approx 0$):

$$\mu_{f_{gt}}^F - 1 = \left(\frac{\sigma^F}{\sigma^F - 1} \right) - 1.$$

The ratio of the two markups (for σ^F finite and $S_{f_{gt}}^F < 1$) is:

$$\frac{1 + S_{f_{gt}}^F(\sigma^F - 1)}{1 - S_{f_{gt}}^F}.$$

Therefore, the dispersion of relative markups under Cournot competition is increasing in the elasticity of substitution (σ^F), and depends on both this elasticity and the dispersion of expenditure shares.
